SCIENCE AND MORAL REARMAMENT

SINCE the international crisis of last September public attention has been directed time and ain in letters to the Press and in other ways to e need for rearmament in the moral sphere. The ovement and the interest in it have undoubtedly rung from a feeling that a critical point has been ached in the history of our civilization, and that ere is danger of disaster unless certain changes the psychology of nations can be brought about.

The movement was by no means confined to reat Britain. Early in June this year a National eeting for Moral Rearmament was held in ashington to which addresses were sent, not only prominent American citizens, but also by memrs of the House of Lords and of the House of ommons, by British Labour leaders, from orthern Ireland, from Scotland, and from a umber of European countries including Switzernd, Holland, Norway, as well as from a number political and cultural leaders in the Balkans. n this occasion the message from ex-President oover was particularly urgent. "The world has me out of confusion before," he wrote, "because me men and women stood solid. . . . They ood firm because they individually held to rtain principles of life, of morals, and spiritual lues. These are the simple concepts of uth, justice, tolerance, mercy, and respect for e dignity of the common man." The message om Mr. Cordell Hull, the Secretary of State, ruck the same note of urgency: "Here in the st-war period there has been a general lowering standards of conduct—moral, political, social, d economic. International morality has seldom en at a lower ebb. The time is ripe and the need urgent for a renewal and restoration of the rmer high standard of conduct of both individuals and governments."

A month later, a World Assembly for Moral Rearmament in the Hollywood Bowl, California, was attended by 30,000 people, and it is estimated that 10,000 were turned away. Twenty-five nations sent representatives, and there was a joint meeting for Chinese and Japanese. Once more a remarkable series of addresses was sent. A manifesto signed by 60,000 British citizens, and messages from artists, labour leaders, educationists, and men of science were among those received. A message signed by seventeen distinguished British men of science runs as follows:

"All who are engaged in the increase of Natural Science are necessarily interested in Moral Rearmament. The effect of the new knowledge which is gained by the study of Nature depends upon the spirit in which it is received and used. Men of good will can make a glorious blessing of it, if they act with wisdom and skill; but ill will and folly can draw from it a curse. Most earnestly, therefore, do we pray as scientists for the success of your coming conference."

This manifesto is to be warmly welcomed as evidence that men of science are alive to the supreme importance of moral issues. We have in these columns frequently directed attention to the lag which exists between the progress of scientific investigation and the ethical advance of mankind. Scientific advance has been more rapid than ethical; indeed there is, as Mr. Cordell Hull said, evidence of actual ethical decline. It is on this account encouraging to note that men of science are not disposed to ignore ethical problems on the specious ground that these lie outside their province. The ethical advance of mankind badly needs speeding up, and men of science are evidently prepared to take their part in applying the necessary stimulus.

We hear much of the increasing specialism of modern scientific study; yet men of science are citizens and human beings as well as specialists, and as such it is incumbent upon them to seek to put an end to the present confusion. Their duty in this respect is all the clearer on account of the general respect in which their pronouncements are held. No other class of intellectual guide enjoys the same public confidence; neither journalists, bishops, literary men, educationists, nor professional philosophers have the ear of the people to the same extent. Furthermore, men of science are only too well aware that the future development of science is inextricably bound up with the survival of certain moral standards and values, such as disinterested love of truth, toleration for new opinions, and so on. If scientific researches are ever subordinated to utilitarian or propagandist ends, the fate of science will be sealed, for in the cultural sphere segregation is impossible.

It may be that the public is entitled to look to the men of science for something even more fundamental than ethical guidance. Mr. Hoover's message spoke of salvation coming from those who "individually hold to certain principles of life, of morals, and spiritual values". Likewise a message from British educationists to the World Assembly stressed the need to equip people with "simple and absolute moral standards". But principles and standards logically rest upon convictions; they fit into a framework of ideas which form an organic whole. But the trouble now is that this framework has been loosened and some parts of it are missing. Is it possible for men of science to tighten up and repair this framework, or if that is no longer possible, to provide us with a new one? Men of science were in no small degree responsible for weakening the traditional framework; can they not now turn from a destructive to a creative role? It would be a thousand pities if their ever-increasing specialism caused men of science to eschew fundamental problems altogether, and to become mere "intelligences within high walls".

Lately, we have received from Prof. T. D. A. Cockerell, of the University of Colorado, a communication which shows that the mind of at least one man of science is trying to think out some of the implications of new knowledge. "It comes to this," he writes, "mankind has evolved, with all his wonderful powers, and with his emerging sense of right and wrong, and of the value of personality. Especially does it seem incredible to us that the attributes of the human mind should be uniquely the property of a little organic slime on a infinitesimally small fragment of the matter i the universe. Hence we postulate a greater min and wonder about it, as a couple of cells in th body might (were they suitably endowed) wonde whether they were part of something greate without being able to reach a decision that wa capable of demonstration. I cannot bring myse to believe that the human mind is a purel ephemeral and essentially quite unimporta phenomenon in a vast inanimate universe.

Thoughts such as these must have occurre to many scientific workers in their speculativ moments, and it would be a pity if all such ide were dismissed as idle and irrelevant to the wor in hand. There is no good reason why men science should place themselves under a sel denying ordinance whereby all philosophical spec lation is taboo. Now that academic metaphysi has become as technical a subject as the high mathematics, the public have need of a philosoph which conveys some meaning to their mind There is no call for men of science to dogmati in the philosophic sphere; which they are n likely to do, being chary of dogmatism in the own. All that the public requires of them is som measure of guidance as to the nature of the univer of which we form a part.

In one respect, as Prof. Levy has pointed ou the man of science has the advantage of th philosopher. Whereas the latter only profess to tell us what the world means, the former te us what can be done with it. His outlook is ther fore practical; and on this account it ma actually prove that his philosophical speculation however unacademic, are nearer the mark tha those of his metaphysical colleague. There is mu to be said for the view that the human intellect is tool devised for dealing with our material enviro ment, and is most reliable when it is thus engage Divorced from action on the environment, t human intellect turns in on itself and functio as uselessly as a squirrel in a cage, or as the engi of a car before the clutch has been let in.

At the present time there is too much defeatis about with regard to science. Its potentiali have become so great that people are afraid of Such defeatism would have small chance of sprea ing if men of science would take the public in their confidence, and tell them what science c do for men of good will. Those who understa science best know that what we are suffering fr is not too much of it but too little.

THE STUDY OF BRITISH VEGETATION

The British Islands and their Vegetation
By A. G. Tansley. Pp. xxxviii + 930 + 162 plates. Cambridge: At the University Press, 1939.) 45*s.* net.

THE subject of plant ecology, like the science of which it forms a part, began as a purely escriptive study concerned with the natural or emi-natural aggregates of diverse species that onstitute plant communities, instead of with the onceptual aggregates of similar individuals that re the concern of the taxonomist. Moreover, in ts inception the study of plant communities was ainly floristic. The pioneers in Great Britain ere the brothers Robert and W. G. Smith and t was at the latter's house in 1904 that the Central ommittee for the Survey and Study of British egetation had its inception. This gave place to he British Vegetation Committee and this in urn, nine years later, was replaced by the British cological Society with the *Journal of Ecology* as s official publication.

No one has done more to promote the study of hytogeography in Great Britain than the author f the work under review. As editor of the *Journal f Ecology* for more than two decades, Prof. Tansley id more than any other single person to organize nd stimulate interest in descriptive ecology, and he bulky volume before us is a fitting culmination o the author's work in this field.

The British Vegetation Committee consisted of small group of enthusiasts which, besides W. G. mith, included C. E. Moss, F. W. Oliver, A. G. ansley and T. W. Woodhead. In 1911 Tansley rganized an excursion in Great Britain for the enefit of foreign men of science, and with the elp of other members of the Committee prepared he handbook entitled "Types of British Vegetaion". The book was definitely static in its method f presentation, although F. W. Oliver's investiations on maritime habitats had already given n impetus to the dynamic approach to the study f vegetation.

"Types of British Vegetation", which Tansley dited, at once achieved popularity. It was the nly publication then available on the subject, it as well illustrated, handy in size and very low n price. Unfortunately the edition was quite mall and the book soon became a second-hand arity. Now, after the lapse of more than a quarter f a century, Prof. Tansley has provided us with nother work, also essentially descriptive in haracter, but the scope of which has been greatly xtended beyond that of the volume it replaces. The floristic aspect is still prominent, and extensive lists of species are furnished; but the structure of the communities and their successional relations receive much fuller treatment. It is perhaps inevitable that the present work is neither small nor inexpensive.

As the author himself emphasizes, the work is largely a compilation of abstracts from the published literature and as a consequence there are certain gaps which one would like to have seen filled. The interesting vegetation of the limestone pavements, for example, has similar meagre treatment as twenty-eight years ago. We regret, too, the omission of the vegetation of arable land and disturbed soil, especially as there is available a not inconsiderable, though admittedly rather scattered, literature on the topic. For, despite their semi-artificial character, such have an important bearing on the early stages of succession.

The first section of the book treats of the environmental complex, the physical features, geology, climate, soil and biotic conditions. The chapter on soil is somewhat academic and might with advantage have been more directly related to the structure of soils as they occur in Great Britain. The attempt to place British soils into systems of classification devised for regions of more differentiated climates is not without its dangers for, as has been emphasized by Glinka, the soils of Britain can be regarded as aclimatic and, as Sir John Russell has pointed out, cannot read ly be fitted into existing schemes of classification. The section on prehistory is a useful summary of the data furnished mainly by the study of sub-fossil remains, especially of pollen distribution.

Part 3 treats of the nature and classification of vegetation types, whilst Parts 4–9, representing nearly three-quarters of the entire work, are devoted to the detailed description of the various categories of plant community. The method adopted is an approach to the type system, summaries being furnished of the published accounts of particular examples. Partly owing to the nature of the areas which have been investigated, the picture presented is sometimes a rather partial one. This is very noticeable in the account of the vegetation of ponds and is sufficiently emphasized by the entire absence, from among the species cited in this connexion, of such characteristic plants as *Alopecurus geniculatus* and *Bidens cernua*, or of any mention of the Juncetum dominated by *Juncus inflexus*, so characteristic of the margins of ponds in the stiffer and more basic soils.

The work as a whole, which is profusely illustrated with half-tone reproductions, many of which are of great merit and technical excellence, is not merely a valuable survey and a monument of what has been accomplished during the past thirty years, much of it under the stimulus of Tansley's initiative, but also an indication of the gaps that still require to be filled. Whilst there still remains much work that can be carried out in descriptive plant ecology in Great Britain, it is probably true to say that such studies, though they may reveal new manifestations, are unlikely to yield new principles, and in this sense the work before us may be said to mark the closing of the purely descriptive phase of the study of Britis vegetation. Future progress lies rather in th direction of causal ecology, of the study of th biological relations of species, and in the applicatio of the principles of physiology and the factors c competition to the elucidation of the problems o plant and animal life under natural and semi-natural conditions. But, with the advent of such knowledge, many segregations and doubtless new syntheses of communities will become necessar before we can attain to a classification of vegetatio types that will adumbrate both the great diversit of organization and the similitude of environmenta factors.

E. J. SALISBURY.

KEPLER'S APPROACH TO OPTICS

Johannes Kepler Gesammelte Werke
Herausgegeben im Auftrag der Deutschen Forschungsgemeinschaft und der Bayerischen Akademie der Wissenschaften. Unter der Leitung von Walther von Dyck und Max Caspar. Band 2: Astronomiæ Pars Optica. Herausgegeben von Franz Hammer. Pp. 466. (München: C. H. Beck, 1939.) 9 gold marks.

WITH the appearance of the second volume of the new edition of Kepler's works the first three volumes are now available, the third containing the "Astronomia Nova" having been issued first in order of date. It is curious that the three already exhibit the complex personality of Kepler in a violently contrasted way. In the first, the mystic element is predominant, and that is hard to reconcile with a truly scientific spirit. The second reveals the impatience of a sanguine temperament, which is not easily compatible with a philosophic outlook. The third, equally the product of those active years which followed the death of Tycho Brahe, reflects an assured serenity, when insight and resource never fail and every difficulty is met and overcome with untiring industry. No voluminous writer can be expected to produce a succession of masterpieces of the highest order, but in the inequality of his work it would be hard to find a parallel to Kepler.

The first words of the lengthy title are "Ad Vitellionem Paralipomena", and they cover the contents of the first part of the book now reprinted. The sources of Kepler's knowledge of optics may be briefly indicated. The most important contributions to the subject by the ancient world were contained in works attributed to Euclid and Ptolemy. These, sharing the common fate of such books, were lost to Europe in the following age, but were preserved in an Arabic form. The study was thus kept alive until th Arabian astronomer known as Alhazen (d. 1038 wrote a text-book on it. It was not until th thirteenth century that interest in optics reappeared in Europe. A text-book, "Perspective" based very closely on the work of Alhazen, wa then written by a Pole (or Thuringian), Witelo (the Vitellio of Kepler). A slighter but simila work, a "Perspectiva", was also written in the same century by John Peckham, who became Archbishop of Canterbury (referred to by Keple under the name Pisanus). It was these books which were printed in the sixteenth century, and that of Witelo was the main source of Kepler's knowledge of the subject. He refers also to the work of della Porta, but the earlier and more important work of Maurolycus in Italy was not accessible to him.

The present editor is very careful to insist on these limitations to the knowledge inherited by Kepler from his predecessors. They may be accepted. But it does not follow that the knowledge of optics, practically that of the year 1000 was equally circumscribed in the world at large Apart from the Italian school, the craftsmanship of the Dutch lensmakers may be recalled for two reasons. By universal tradition it was from Holland that Galileo derived the suggestion for his telescope. It is also scarcely necessary to look further for the inspiration which in turn guided Snell, Descartes and Huygens in optical research

But in England also, the study of optics had not been altogether neglected. Already in the thirteenth century Roger Bacon had done work o a very different order from the compilations made by his contemporaries. That work was transmitted in manuscript form to Leonard and Thomas Digges and John Dee in the sixteenth century hese men formed a group working independently f any Continental tradition, and yet not isolated, nce they were known to Tycho Brahe, as Harriot few years later was known to Kepler. Thus search in optics had been kept alive to such an xtent that Harriot was able to supply himself nd his friends with telescopes; but it remains true hat the progress made had taken a practical shape nd the results had not been published in the rinted form. In consequence, some things which epler claimed as new were not so original as he pposed.

The book follows a most comprehensive plan. t includes geometrical optics, physiological optics, nd in the second section deals with a variety of stronomical matters such as eclipses and problems f parallax which would now be considered alien o the main subject. In the circumstances of the ime, there was plainly an opening for a new work n geometrical optics, and the needs of astronomy rompted a careful consideration of the subject, nore particularly for the investigation of astronomical refraction. With these motives and with a ertain amount of material in hand, Kepler tarted on his task early in 1603. He seems to ave worked to a self-imposed time-table. The ork was to be finished by the end of the year nd to be published in the following spring. It id appear in the following autumn, and in view f modern conditions, there seems little reason for omplaint on the score of delay in the production f a large volume.

The project may have been justifiably optimistic r foolishly arrogant, according to the point of iew. In any event, the difficulties of the task ecame more and more apparent, and as they rew Kepler became more impatient. This is hown in his correspondence and it is abundantly lear from internal evidence. Ideas are started nd carried to no logical conclusion. Passages hich should have been re-written were merely mended in a hasty way. But Kepler persisted nd the book was finished within the year. He new the eager and uncritical public for whom he atered. But his own interest in the subject was robably waning.

For this, two reasons may be readily conjectured. he first one and the more important excuse for is impatience was the urgent call of that other ork which was the true mission of his life. Hence he adherence to a time limit. But he must also ave become aware that the conditions were npropitious for the production of a "Markstein weiter [or any other] Ordnung". What the science f optics at that time plainly needed was a foundaion in accurate experiment. This was entirely acking. Now Kepler was himself no experimental hysicist, and he had no source from which he could draw what was necessary. The experimental data at his command were incredibly slight, and he must have become conscious of the fact.

This applies in particular to the capital problem of the time, the determination of the law of refraction. Kepler's formula is

$$\alpha - \beta = k \alpha \sec \beta,$$

where α is the angle of incidence, β the angle of refraction. With $(1 - k)^{-1} = n$, this gives results similar to the law

$$\sin \alpha = n \sin \beta$$

for the smaller refractions. The constant k for air-water is based on the assumed values $\alpha = 80°$, $\beta = 50°$ (more than 2° in error). As the formula is really empirical, being founded on the flimsiest physical argument, it seems strange that a form so inconvenient for the derivation of β from α should have been adopted. The relation also seems inconsistent with the most obvious principle of optics, the reversibility of the ray.

Passing on to the problem of astronomical refraction, Kepler was in a position of complete ignorance as to the nature of the atmosphere. He assumed that it was homogeneous and ultimately fixed its height at about 4 km. Tycho Brahe had left three separate tables of refraction for the sun, moon and stars, and Kepler found it impossible to represent the solar table in spite of repeated trials. He therefore resorted to the original observations of Tycho and found material which removed the difficulty. Thus he succeeded in constructing a table of refractions which has been found superior to those of Tycho. But the advance must be regarded as belonging to astronomy rather than to optics.

The present editor's analysis and notes are of great value. If a rather lower estimate has been placed here on the intrinsic importance of Kepler's book, it is in the belief that the time was not ripe for the production of a major work. It was the threshold of a period of great advances in optics, but for the moment the knowledge which could only come from experiment was lacking. When Harriot supplied a list of angles of refraction with angle of incidence 30° for no less than fourteen media, with the corresponding specific gravities, and pointed out that there was no direct relation between refractivities and densities, quite characteristically Kepler argued against the evidence. He might have learnt more about optics from Harriot, as he might have learnt something about the sidereal universe from Digges, and Wallis was not far wrong in his general thesis that early English science had not met with due recognition on the Continent.

(5) Adaptation in Pathological Processes

By Dr. William H. Welch. Reprinted from Transactions of the Congress of American Physicians and Surgeons, 1897, Vol. 4, pp. 284–310. With an Introduction by Dr. Simon Flexner. (Publications of the Institute of the History of Medicine, the Johns Hopkins University. Fourth Series: Bibliotheca Medica Americana, Vol. 3.) Pp. xi+58. (Baltimore, Md.: Johns Hopkins Press; London: Oxford University Press, 1937.) 7*s*. net.

(1) IN his work on early medieval medicine Prof. C. MacKinney, who occupies the chair of medieval medicine in the University of North Carolina, gives a richly documented account o medicine in that portion of the Middle Ages extending from the sixth to the eleventh century. Durin that period two distinct types of medicine wer prevalent, namely, the supernatural, which included reliance on Christian saints and their relic Christian-Pagan charms and magical incantation and human medicine, which consisted chiefly o empirical methods of healing mainly by drug surgery and diet. Of the three lectures containe in the book the first deals with the changin modern conceptions of the Middle Ages formerl regarded as stagnant and unproductive but no looked upon as an era of vigorous activity.

In the second lecture, in which Prof. MacKinne discusses medicine in Merovingian and Carolingia France, it is shown that in the Merovingian ag comprising the three centuries before Charlemagn there was a steady advance in France in medica practice which was accelerated during the tent and eleventh centuries. Although the outstandin methods of medical practice at that time were a before blood-letting, diet and herbal potions, th clergy became more interested in medical condition and took a much more active part in carin for the sick.

In the third chapter, which is devoted to medica progress at Chartres in the tenth and eleventh centuries, extracts from the works of Gerber Richer and Fulbert illustrate the separation o medical practice from mere book knowledge. Sixt pages of notes and photographs of medical manuscripts are appended to the text.

(2) Dr. Ramon Pardal's work which forms par of the series edited by Dr. Imbelloni, who contributes the preface, is divided into four part devoted respectively to medical ethnology, medicine in ancient Peru and Mexico, stimulating narcotic and hallucinating drugs, of which the chie are coca, maté and peyotl, and American drug in modern medicine. In the first part the autho shows that the medicine of the American India was of a primitive character, based on magi therapeutical empiricism and the surgery c emergencies. The practitioner in those times wa esteemed rather for his magical power than fo medical knowledge. It was only among the people possessing a relatively superior feudal organizatio such as the Incas and Aztecs, that the elemen of a higher order appeared and the functions c priest and doctors were separated. The secon part deals with the practice of medicine in ol Peru, with special reference to the operation c

phining and the representations of diseases, ecially syphilis, on pottery. The drugs used modern medicine for which we are indebted to natives of South America include the balsams Tolu and Peru, guiacum (once regarded as a cific for syphilis and now only employed in ut and chronic rheumatism), sarsaparilla (also ed in former times as an anti-syphilitic drug, but w almost confined to quacks who sell it as a ood-purifier'), cinchona, copaiba, pilocarpine and mopodium.

The work will appeal to the anthropologist and ethnologist, as well as to medical practitioners d pharmacologists interested in the history of healing art.

(3) Dr. Thomas Thacher's "Brief Rule", of ich the three editions are published in this little lume, represents the earliest medical document be printed in America north of Mexico. It nsists of a single printed sheet which first ap-ared in 1677–78 and was reprinted in 1702 and 21–22. The author was born in Somersetshire, t migrated with his parents to New England in 35 at the age of fifteen years in accordance with practice of many dissenting ministers and their milies in the early part of the seventeenth ntury. Thacher was brought up to be a clergy-an like his father, but like many of his con-nporaries was something of a physician as well a minister, and enjoyed a considerable practice Boston. A severe epidemic of smallpox which oke out in that city in 1677 causing 700 deaths mulated Thacher to publish his broadside, ich is taken almost word for word from the cond chapter of Sydenham's "Medical Observa-ns". Subsequent outbreaks of smallpox in ston in 1702 and 1721 were the occasion of the rinting of the work.

(4) In the address which is here printed in simile, and was delivered in 1765 in the College Philadelphia, where he occupied the chair of theory and practice of medicine, being indeed e first professor of medicine in the United States, . John Morgan, who had received his medical ucation not only in Philadelphia but also in ndon, Edinburgh, Paris and Leyden, gives a neral survey of the different departments of dicine and describes the existing conditions in nerica, the difficulties accompanying the study medicine and the impracticability of making y great progress until it had been put on a better oting. The preliminary sciences of anatomy, teria medica, botany and chemistry are reviewed d their contribution to the cure of diseases nsidered. The necessity of a knowledge of Latin d Greek for the physician is then emphasized well as familiarity with the French language, ile acquaintance with mathematics and natural philosophy is regarded as indispensable. As regards the contemporary state of medicine in America in 1765, Dr. Morgan deplores the lack of professional teachers to give complete and regular courses of lectures in the different branches of medicine, in striking contrast with the medical schools in Europe which he had visited. He suggests, therefore, that a course of clinical practice and clinical lectures by physicians of knowledge and experience should be established to remedy this deficiency, and recommends the foundation of a medical library. He himself proposes to give a course of lectures on materia medica followed by one on the institutes and theory of medicine. Next he urges that the activities of physician, surgeon and apothecary should not be combined in one man, but asserts that "practitioners would enjoy much more satisfaction in practice if physic, surgery and pharmacy were in different hands". Finally, he dwells on the advantages which American students have over those in Europe in possessing an ample field for the study of natural history.

(5) Dr. William Welch's address, which represents the presidential oration delivered before the Congress of American Physicians and Surgeons in 1897, is, as Dr. Simon Flexner remarks in the introduction, as applicable to the subject to-day as it was forty years ago. Dr. Welch maintains that pathological adaptations have their foundation in physiological processes or mechanisms. Pathological adjustments, however, lack the co-ordinated fitness characteristic of physiological adaptation, as he illustrates by the case of a heart hypertrophied in consequence of a vascular lesion which does not completely restore the normal condition of the circulation. Similarly, a kidney hypertrophied in consequence of deficiency in the other kidney is more susceptible to disease than the normal organ. While adaptation is usually to some extent advantageous to the individual, it is not necessarily so, as is shown by a scar in the brain causing epilepsy. Throughout his address Dr. Welch emphasizes the importance of taking into consideration not only the facts of human and allied physiology but also those accumulating in the domain of experimental embryology and morphology, especially as regards the influence of various changes of environment, particularly of definite chemical, thermic or mechanical changes upon the movement or growth of cells.

In conclusion, Dr. Welch points out that systems of treatment based exclusively on the theory of the *vis medicatrix naturae* often rest on an insecure foundation, inasmuch as the agencies employed by Nature may be either inadequate or entirely helpless.

J. D. ROLLESTON.

A STUDY OF HUMAN RELATIONS

Man the Slave and Master

By Mark Graubard. Pp. x+366. (London: J. M. Dent and Sons, Ltd., 1939.) 10*s*. 6*d*. net.

TO-DAY, as never before, the man of science is faced with the problem of the relation of science and society. Science is a powerful weapon for evil as well as good, and it is the business of the man of science to ensure so far as he can that his work is not misused. One of the great difficulties of such a task is that few modern men of science are well informed outside their own fields of work. Still more is the layman ignorant of science, especially in that he is seldom acquainted with that manner of approach which is often termed the 'scientific method'.

Dr. Graubard has set himself the task of helping to remove this difficulty by presenting, in simple terms, an analysis of human behaviour and the composition of society based on biological knowledge. He discusses conditioning, heredity and evolution, both biological and social, and he does it in a way that should commend the book to men of science and laymen alike. He then turns to the application of his knowledge to the scientific control of human affairs, and though at this stage it is inevitable that some disagreement must ar his analysis and proposals can be read with pr even by those whose views diverge most.

It is a pity that the book is marred in places occasional inaccurate and loose statement. In account of Mendel's work with peas, the round wrinkled characters of the seed are described determined by the mother plant's constituti whereas they are, in fact, dependent on the ge type of the zygote itself. His implications th Mendelian inheritance in animals was first served in rabbits and that departure from Mend second law, of independent assortment, was f found in Drosophila, show a lack of appreciat of Bateson's work with poultry and sweet pe On p. 190, the author says "Hence they [that all the races of man] form a species" and on p. "the Negro, who of all the species of man has least hair". Other similar examples could quoted.

These are, however, minor blemishes and sho not be allowed to obscure the fact that Dr. Gr bard has written a valuable book, at once criti and informatory. It should be read by all who interested in the study of human relations.

K. MATHER

CONSERVATION OF NATURAL RESOURCES

Conservation in the United States

By Prof. A. F. Gustafson, Prof. H. Ries, Prof. C. H. Guise and Prof. W. J. Hamilton, Jr. Pp. xi+445. (Ithaca, N.Y.: Comstock Publishing Company, Inc., 1939.) 3 dollars.

THE conservation and the restoration of its natural resources are perhaps the most important questions that the United States has to face. These are here divided into sections dealing with the soil, forests, wild life and minerals, especially coal and oil. Each is written by an expert who has researched with the view of ameliorating the present difficulties. Perhaps their most interesting feature is the close connexion, never stressed but everywhere made plain, between purely scientific investigation and the practical problems. This is as it should be, as the work is intended to be a text-book to stimulate students who have already had a broad scientific training. It everywhere sets out the historical facts, present position and the possible and desira remedies so far as the necessities induced increase of population allow.

While mineral resources may be regarded waning assets merely to be treated with the great economy, the soil and water are as necessary man's existence to-day as in all ages. Passing o a section dealing with the topography of the coun and the consequent production of soil regi of varied productivity, these always associa with water, there arise questions of soil deplet by the loss of plant nutrients and of erosion los due to wind and rain. The white man found eastern part of the country unbroken forest wh had to be cleared for crops. Organic mat disappeared from the soil so that its surface carried away by the rainfall, already half the soil being lost by this means over an area estima at 855 million acres. Another 322 million acres eriously depleted by wind erosion, so that nearly wo-thirds of the country is affected. Remedies uggested are in the due employment of green manures, crops to be ploughed in to hold the water in the soil, and schemes of planting that will tilize the rainfall rather than encourage the ormation of gullies, methods excellently shown n a series of photographs. These must be associated with considerations of the conservation nd reafforestation of the woodlands, a problem f great complication since a large country is ivided into many vegetative regions dependent on temperature, wind, rainfall and subsoil, each rea with its own trees and undergrowth. Forest fires must be controlled, while waste in the lumber ndustry has to be avoided. Fortunately the questions here have become national, though the ndividual States and even counties are helping, appreciating the local effects on rainfall and the value of such wooded parks to the psychology of heir own people. The national forests now aggregate 170 million acres, and the aim appears o be to double this amount by the planting of he high lands but mainly of the abandoned arming areas, and in this way reclaiming immense wastes.

The section dealing with the animal resources, fish, birds and game, is excellent. The decline of the supply of certain fish was inevitable in an absence of knowledge of their biology, but the Fish Commission has the matter well in hand and has already had striking success in matters of regulation, avoidance of pollution and hatcheries. The buffalo herds have gone for ever, but Pennsylvania has done fine work in the encouragement of deer, while the beavers, reintroduced from Canada less than twenty years ago, have now to be trapped—a new industry.

While in this study of the United States much is local, the analogy with Africa is striking, the terrain very similar. European countries start there with the experience of America through three centuries. This suggests the necessity for paternal governments to control unthinking settlers so that the land may not be impoverished. It may not ever require to be developed as that of the United States, but it will undoubtedly have to provide food for a teeming population. So far the agriculture of native areas is small, but the cow as the unit of wealth is disappearing and a certain change of habits in the native population must occur. The thoughts which are induced by this study of America should excite the imagination of all who have to rule in Africa, where clearly it is already time for regularized conservation.

J. Stanley Gardiner.

FOUR-TERMINAL NETWORKS

Einführung in die Vierpoltheorie der elektrischen Nachrichtentechnik

Von Prof. Dr. R. Feldtkeller. (Physik und Technik der Gegenwart, Abteilung Fernmeldtechnik, herausgegeben von Prof. Dr. Heinrich Fassbender, Band 2.) Pp. ix+142. (Leipzig: S. Hirzel, 1937.) 3.80 gold marks.

THIS is an excellent introduction to the comparatively young theory of four-terminal networks, that is, of alternating-current transfer systems of which only the input and output pairs of terminals are accessible for measurements. After a brief outline of network analysis, the author passes in Chapter ii to a thorough theoretical investigation of linear symmetrical four-terminal networks, of which the behaviour for different terminal impedances is examined by means of circle diagrams based on the network parameters. The application in Chapter iii of this theory to the particular case of loss-free systems illuminates the theory through the relative simplicity of the circle diagrams required, while Chapter iv deals with asymmetric linear systems.

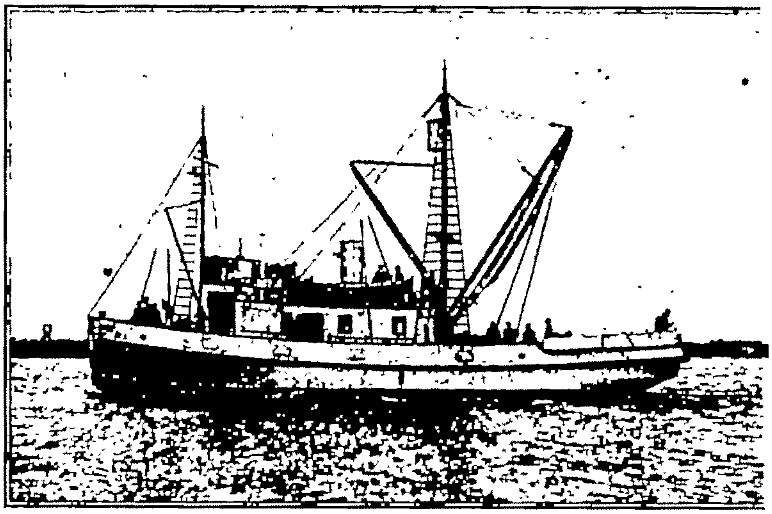
Chapter v treats the general theory of linear four-terminal networks by the use of matrix algebra, a field of electrotechnical advance in which the author was a pioneer. With this treatment, as the author remarks, the book passes from text-book to hand-book, and the two final chapters provide at once the tabular material for, and a demonstration of, the labour-saving use of four-terminal theory in matrix form. Matrices are derived for the fundamental interconnexions of the four-terminal networks, and the theory of propagation networks in cascade is touched on. In the sixth and last chapter are collected the matrices of simple four-terminal structures, including transformers and (linear) amplifying valves, while a final section shows the derivation of equivalent *T*- and π-networks for systems obeying the Kirchoff reciprocal principle, and for systems not so restricted.

The book is clear, neat and detailed; the few errors that have escaped the proof-reader are mainly of interest as evidence of revision by the author in the interests of clarity.

FISHERIES RESEARCH IN AUSTRALIA

BY SIR DAVID RIVETT, K.C.M.G.

SINCE the ill-fated trawler *Endeavour*, under Dr. Dannevig, was lost at sea in 1914, fisheries exploration has rather languished in Australia. This is scarcely pardonable in a country with 12,000 miles of coastline, a relatively poor fish supply, especially in the inland areas, and a definite need for quantities of fish meal on its stock farms. During the past two years, a vigorous effort has been made to improve matters under the Council for Scientific and Industrial Research working in co-operation with universities (particularly that of Sydney) and State Departments.



M.S. *Warreen*.

Dr. H. Thompson, formerly of the Newfoundland Fisheries Services, has been appointed officer-in-charge of investigations, and under his guidance the Station illustrated in the accompanying photograph is nearing completion. The site, made available by the New South Wales Government, is that of Dannevig's hatchery at Cronulla, the southernmost Sydney watering-place, on the Port Hacking estuarial group of salt-water inlets. It is admittedly a very beautiful spot for a marine biological station, with deep and shallow water frontages of rocky and sandy foreshores. Museum and library facilities are easily accessible in Sydney; and the fish market there will be useful in the collection of biological material and statistics from the trawling and seine-netting fleet.

MARINE BIOLOGICAL RESEARCH STATION, CRONULLA.

The aquarium and offices are in the left foreground and the main laboratory building in the right Behind are the concrete tanks. On the shores are the pond and boat sheds.

The pre-existing hatchery appointments have been converted for experimental work. Salt water is pumped to a 25,000 gallon concrete tank and fed by gravity to an aquarium where the temperature is under control. A large tidal concrete pond (100 ft. × 42 ft.) has been reconditioned for the retention of fish for observation or experiment. New additions include a workshop, net- and fish-cleaning shed, and a main building containing offices, stores, biological, chemical and bacteriological laboratories, dark-room, charting and drawing room, and a large library. Refrigerating cabinets and a small canning plant are provided.

A 16-ft. motor skiff has been built for local sampling work and a 2-ton truck has been equipped as a mobile laboratory.

For exploratory work, mainly on pelagic, or urface-swimming, fish, M.S. *Warreen* (a native ame for the sea) was built in Melbourne and has een in commission for about fifteen months. She 82 ft. long, of 108 tons displacement, and is ted with a 215 h.p. main engine of Atlas Polar iesel construction, with Ruston auxiliaries. She rries radio equipment for transmitting and ceiving, and an echometer for automatic record- g of depth. A small laboratory permits limited ork at sea. A large purse-seine net is carried on turn-table in the stern.

Over so great an extent of sea, one small vessel capable of a speed of only 9 knots can do but little: hence very full use is being made of reconnaissance from the air. Aircraft and personnel are made available to the Council by the Royal Australian Air Force; and particularly in the 'spotting' of shoals of tuna and so-called salmon (*Arripis trutta*), air observation has been conspicuously successful. Already possibilities have been demonstrated which are attracting the attention of commercial men; but a great amount of scientific investigation will be necessary before a sound basis for fisheries development is secured.

STRUCTURE OF THE RAYON FIBRE

By Prof. H. Mark

REFERENCE has frequently been made in these columns[1] to the progress of our knowdge concerning the structure of natural and rtificial fibres during the last few years. The ccompanying illustration (p. 314) gives a résumé f the present state of knowledge as represented y the cellulose fibre, which is very well known nd at the same time of great economic imporance.

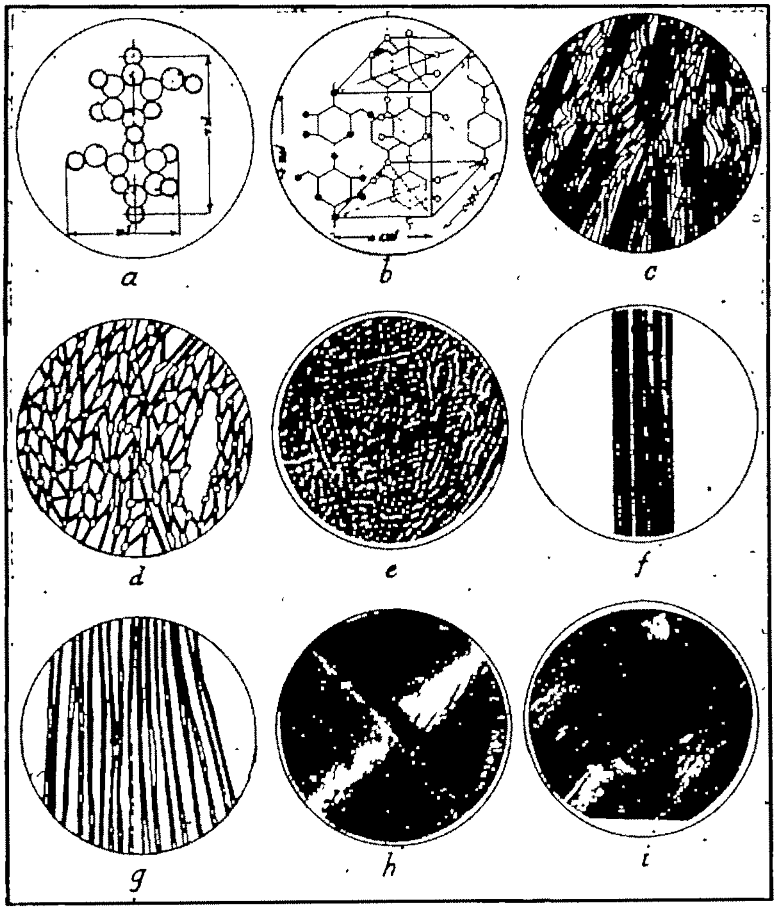
The illustration was made up under the assumpion that we have at our disposal a microscope llowing us magnifications of unlimited amounts n such a way that we can always increase its esolving power by the factor of 10 by switching in nother imaginary objective. Looking at a rayon hread through such a microscope, we should btain such a series of pictures, and it seems esirable to discuss them one after the other and o point out what kind of information they give nd to what extent the particular qualities of the bre are shown by them.

(*a*) We start with the highest magnification, bout 1 to 50,000,000, and observe the ***fundamental hemical unit*** of cellulose, namely, the ***glucose residue*** omposed of 6 carbon atoms, 10 hydrogen atoms nd 5 oxygen atoms[2]. These glucose units have a ing structure and are linked together by main alence bonds. They stand for the chemical beaviour of the material, for example, for the fact hat cellulose is easily wetted and swells in water, ut does not take up organic substances such as etrol, benzene or oil. They are also responsible r the fact that one can produce certain derivaives of cellulose, namely, cellulose nitrate (celluid), cellulose acetate (cellon), etc. Finally heir presence is responsible for the fact that by hydrolysis cellulose can be converted into a sugar.

(*b*) We pass now to the next magnification, 1 to 5,000,000, and get an insight into the ***crystallographic unit*** of the fibre. What we see is the ***elementary cell*** of the cellulose lattice revealed by X-ray investigations[3]. We see that the different glucose residues are united to long chains lying parallel to each other and running through the fibre along its axis. The presence of these long and highly orientated chains explains the double refraction of the material, its high mechanical tenacity, the anisotropy in swelling and the behaviour towards substantive dye-stuffs.

(*c*) When we switch in a magnification of 1 to 500,000 we get the next picture. Here each single chain of diagram *b* is represented by a thin line. We learn that these chains are partly bundled together with a considerable degree of order forming a ***micellar structure***, and partly they represent a complicated framework of entangled fringes[4]. We get the impression that the whole fibre consists of parts with comparatively high crystallographic orientation and of other parts which can be called amorphous. This peculiar structure accounts for the fact that rayon fibres at the same time show a considerable strength and a high elasticity. It is responsible for the amount of swelling, the dyeability, and the resistance to creasing. Every process that aims at producing rayon has to take account of this fact.

(*d*) The next step, leading to a magnification of 1 to 50,000, gives a more general view of this ***fringe and net structure*** of cellulose. In *d* the parallel strokes represent the crystallized areas while the small irregular circles are the amorphous regions. We see that the fibre may be regarded as an irregular flexible net built up of these two units and exhibiting at certain places larger holes which, of course, are in some way due to the origin of the material[5]. This structure is in general connected with the mechanical properties of the thread with its elasticity, plasticity, tenacity and its chemical reactiveness. The spaces and crevices between the crystallized areas absorb dye-stuffs, wetting agents and other reacting substances. They are of great importance to the behaviour of the fibre as a textile.



(*e*) We have reached a magnification of 1 to 5,000 and are now at the utmost limit of normal microscopic resolving power. The differentiation of picture *d* has disappeared and we observe a *fibrillar structure* in which the morphological units of the fibre are visible. They may be not so pronounced in artificial filaments and hence the above picture shows the fibrillar structure of a cotton fibre. The length, width and orientation of the fibrillæ are of great importance for all the finer textile properties such as elasticity, softness, lustre, creasability, etc.

(*f*) Switching in the next magnification, 1 to 500, we have finally reached the range of microscopical observation with normal light[6]. The picture shows a *viscose rayon thread* exhibiting system of stripes parallel to its fibre axis. The are responsible for the soft lustre of the yarn, i pleasant appearance, and its easy dyeabilit Pictures such as this are of great importance technical routine tests carried out in rayon factorie The present one, for example, shows little speck indicating that some contamination of the materi has taken place.

(*g*) This picture, with a mag nification of 1 to 50, shows bundle of a normal *viscose rayc thread*. Pictures of such kin are of importance to control th levelness of the yarn, its homo geneity in diameter, colour, dye ability and lustre.

(*h*) and (*i*) The last two pic tures finally give us the wel known aspect of an artificia *silk yarn* with a magnificatio of 1 to 5 and without magnifica tion at all. They need n explanation, being familiar t everyone.

The set of the above nin pictures may offer a certain in sight into the structure of very important substance start ing from the trade product namely, *rayon yarn*, and endin with the last detectable chemica unit, namely, the *glucose residu* The location and understandin of every single structural prin ciple is of importance, for eac influences all the different tech nical qualities of the final pro duct; the better and mor accurate these nine pictures ca be made, the higher will b the probability to make a rayon yarn of bes quality.

POLYPLOIDY INDUCED BY COLCHICINE AND ITS ECONOMIC POSSIBILITIES

BY DR. G. H. BATES,
THE FARM INSTITUTE, PENKRIDGE, STAFFORD

THE technique employed by plant breeders has undergone revolutionary changes since the st workers began the production of new and proved varieties. The methods of the selection-ts, such as Luther Burbank, were certainly ectacular, but they were laborious, expensive d haphazard. Mendelism marked a great step rward, in that it was possible to work along pre-nceived lines in an orderly and economical anner with a fair idea of what was likely to aterialize. There is no doubt, however, that endelian methods have taken us as far as they an, at least in respect of our commonest crop lants. We have exhausted all possible combina-ons of known characters and have reached a oint where, as Salaman has declared, we are mply 'ringing the changes' on existing material. point has been reached where the hybridizer an only wait for some new mutation to turn up.

Attempts have already been made to produce hese mutations by the artificial production of olyploidy. Such practices as thermal treatment, entrifuging and decapitation of the apical shoots the seedling have proved successful in a very nall number of cases. They are, however, far o laborious to be considered worth while.

In view of the above facts, it is small wonder that the discovery by Blakeslee and Avery of the alue of colchicine as an agent for the production f polyploidy has received a great welcome. The eed for such a stimulus has probably accounted or the wave of optimism which seems to have wept through the ranks of plant breeders through-ut the world. Results up to the moment, however, carcely seem to justify the description of the new echnique as being more than promising.

The drug colchicine, prepared from parts of *olchicum autumnale*, has been known to physicians or many years, mainly as a specific for gout. Hope as expressed that it might also prove to have an nhibiting action on carcinomatous cells. It is nly recently that its influence on mitosis has been discovered and put to practical application.

There have been several theories as to the exact manner by which it brings about somatic doubling. t has been suggested that nuclear division takes lace at a greater rate than cell division, under the nfluence of colchicine, thus resulting in bi-nucleate ells with subsequent fusion of the pairs of nuclei. The investigations of Levan, supported to a certain extent by others, have practically established the fact that another mechanism is responsible. It appears that inactivation of the nuclear spindle prevents anaphase reduction, thus leading to a doubling of the chromosome number. Experiment has shown that meiosis is also affected, but this has no economic application as has the influence on mitosis.

The exact action of colchicine and the mechanism by which changes are effected has great interest for the cytologist. However real may be the achievement in this direction, the practical plant breeder is more concerned with the accomplished fact and its possibilities.

Literature on the subject has already assumed large dimensions and results pour in from all parts of the globe. The number of workers is now so great as to make a detailed account of their different activities impossible in a small space. A review of available publications leaves one with the impression that, in the main, reports are fragmentary and often unconvincing.

Easy and rapid methods for identifying the polyploid condition are certainly desirable; but it is doubtful whether they are, as yet, sufficiently trustworthy to be used in proof of claims made for the results of a new and revolutionary technique. One could wish that statements were supported by something more concrete than such criteria as pollen grain size, dimensions of the stoma guard cells and *gigas* characters. On the other hand, claims for the production of tetraploid plants of several species are made which are supported by chromosome counts. It must be conceded that the work is as yet in its infancy, and technique is by no means perfected.

The practical application of the treatment has taken different lines and there are several methods for the administration of the alkaloid. The soaking of the seed in dilute solutions varying in concentration from 0·05 to 1·0 per cent is the commonest practice. The influence upon the seedling depends upon such factors as the concentration of the solution, period of soaking, nature of the testa and the rapidity with which the seed germinates. In some cases it is suggested that the testa should be removed or that the seedling itself should be treated.

A large amount of routine work is necessary to determine the optimum concentrations for the seeds of different species. I have found that a 0·05 per cent solution has a profound influence on the seedlings of mustard after soaking the seed for four days. In the case of several gramineous species the seed of which had been treated in like manner, only a very small proportion of individuals was visibly affected. In the case of sweat peas, the seeds either failed to germinate or the distorted seedlings perished.

The main objection to seed treatment is that germination is either partially or completely checked, root development is restricted or absent for some considerable time and a great waste of material occurs. There is a characteristic swelling of the hypocotyl, more notable in some species than in others. Many odd distortions occur, each characteristic of a particular species

The treatment of apical and axillary buds has produced tetraploid shoots. This is affected by painting on the solution, in combination with a wetting agent, by spraying or by immersion. A 0·4 per cent solution is recommended by American workers for the direct application method.

Spraying of the parts is the least desirable of methods from the operator's point of view. It is important to stress the fact that colchicine is a dangerous drug and that in the hands of irresponsible persons disastrous results may occur. The human mucous membranes are particularly sensitive and one reads of serious eye injuries.

I have employed the 'injection' method as elaborated, for other purposes, by the East Malling workers. A 0·05 per cent solution has been used, a vertical slit in the stem of the plant or a severed petiole being placed in a tube of the solution. Profound morphological changes take place, and, as the influence is localized, its intensity varies throughout the affected part of the plant. In tl case of *Vicia Faba*, the flowers were swollen the base and were all abortive except two. The gave rise to pods showing *gigas* characters with a erect habit of growth. In *Fragaria* species, distorte fruits have been produced. A large amount material has been treated by this method, but is as yet too early to determine whether polyploid has resulted.

Colchicine is an expensive commodity and i vestigations are proceeding to explore the poss bilities of acenaphthene as a cheaper substitut Kostoff has shown that the disintegrating fra ments of the corm of Colchicum can produc polyploidy in germinating seedlings in clo proximity.

Reviewing the whole of the work on induce polyploidy in a dispassionate manner, one mus admit the remarkable nature of the achievement from the cytological point of view. Whether ther will be much material gain accruing to the pla breeder remains to be seen.

In the case of garden plants there are distinc possibilities. Abnormal or distorted varieties wit unusually large flowers have an economic valu with a public displaying an insatiable appetite fo novelty. Food plants are in a different categor Tetraploids are of frequent occurrence, but are no always of special merit ; in fact, the reverse quit often obtains. Increased size is not always o importance, for with most of our arable crops ther are varieties capable of producing plants just a large as the soil will grow them.

We do not, of course, know how the new tetraploid types will react to disease infection, how thei cooking qualities may be affected for better o worse, or how altered morphological character may be of benefit to the cultivator. For th present the chief possibility appears to be th production of fresh material upon which to build

OBITUARIES

Dr. A. Harker, F.R.S.

THE death of Dr. Alfred Harker, emeritus reader of petrology in the University of Cambridge, on July 28 at the age of eighty years has removed from our midst an outstanding figure in British geology—one whose brilliant contributions in his own field over half a century placed him in the forefront of living petrologists.

Born in Hull on February 19, 1859, Harker entered St. John's College, Cambridge, in 1878 and graduated eighth wrangler in the Mathematical Tripos of 1882. He was placed in the first class of both parts of the Natural Sciences Tripos with physics as his chie subject, and was elected to a fellowship in his colleg in 1885. Though not of the 'Bonney School', so muc were his early geological interests strengthened a St. John's that he was eventually attracted to demonstratorship under McKenny Hughes. H became University lecturer in 1904 and on the deat of Hughes in 1917 was elected to a special readershi in petrology.

Harker's earliest papers dealt with the cleavag structure of slates, an investigation for which hi mathematical training peculiarly fitted him. These studies were based in part on his observations on the dates of North Wales, where soon he became absorbed n a new interest—"the petrology of the igneous ocks associated with the Cambrian (*Sedgwick*) ystem of Carnarvonshire"—and endeavoured to race the relationship of the igneous phenomena of he district and concurrently operating crustal tresses, a theme which he was greatly to amplify in is later writings. The results of this work were ncorporated in the Sedgwick Prize Essay for 1888. During 1889–93 he was engaged in the Lake District where, in collaboration with J. E. Marr, he traced a aried group of lavas, ashes and sediments into the ureole of the Shap Fell granite. These papers form pioneer contributions on the nature and origin of metamorphic rocks and rank with Rosenbusch's lassical studies on the *Steigerschiefer* of the Vosges.

With a reputation now thoroughly established, Harker, at the instance of Sir Archibald Geikie, was seconded in 1895 to the Geological Survey of Scotland for summer field work in Skye. The mapping of the mountainous groups of the Cuillins and the Red Hills of central Skye which followed, was completed in 901, and will ever remain as a monument to his skill and ardour as a field geologist, and disposed finally of the embittered controversies of Judd and Geikie on the igneous succession of that island.

The outcome of his researches in Skye, and later n Rum, appeared in two Survey memoirs—"The Tertiary Igneous Rocks of Skye" (1904) and "The Geology of the Small Isles of Inverness-shire" (1908)—and at once attracted wide attention. Considering he time of their execution, and as the work of one ndividual, these researches will always rank as one f the greatest achievements in igneous geology.

The way was now prepared for Harker to present to a wider audience his long-considered views on the broad aspects of magmatic descent and the controlling influence of tectonic environment. These problems, among others, he unfolded in his "Natural History of Igneous Rocks" (1909). Written in an xtremely lucid style and with a rare power of hilosophical generalization, this volume has come o exert a deep influence on petrologic thought. If ome of his conclusions have needed amendment, in s broad lines, his achievement has been none the ess fundamental.

The same philosophic outlook characterized Harker's presidential addresses to the Geological Society. In the last of these he returned once more to the subject f metamorphism, a field which became his dominant nterest in later years. His final work appeared in 932 under the title "Metamorphism", a treatise hich has been appraised in the words of an acknowledged authority as filling "an important place in he literature of petrology, and in lucidity, balance and breadth of view can serve as a model to all future riters on the anatomy and history of rocks".

Harker was elected a fellow of the Royal Society n 1902 and awarded a Royal Medal in 1935. From he Geological Society of London he received in succession the Murchison and Wollaston Medals. Honorary doctorates were conferred upon him by the niversity of Edinburgh and McGill University, hile he was honorary or corresponding member of many scientific societies, British and foreign. These honours he accepted with such extraordinary modesty that many of them remained hidden and unsuspected by even those most intimate with him.

Harker's elementary lectures made little appeal to the average Tripos man, but he excelled in contact with senior students, and his advanced courses became the source of inspiration to many generations of students.

After his retirement in 1931, and to within a few weeks of his death, he continued to devote much time to the care of the petrological collections of the University. In the Harker Collection of rock slices numbering now some 40,000 slides neatly labelled in his own handwriting and representative of research material drawn from all quarters of the globe, he has endowed his department with a unique monument.

At St. John's College, where he had been for some years the senior fellow in residence, he was rather a lone figure, though on his retirement he seemed to cast off some of his natural reserve. By his old pupils he was held in affectionate regard, and the expression of this esteem was signally evoked at the dinner held in his honour at Cambridge on the occasion of his eightieth birthday. Those who were privileged to have his confidence and companionship will retain a lasting memory of the generosity and humility of a truly great man.

C. E. T.

Mr. W. Scoresby Routledge

We regret to record the death of Mr. W. Scoresby Routledge, traveller and anthropologist, which took place suddenly at Paddington on July 31 in his eightieth year.

William Scoresby Routledge was born at Melbourne in 1859 and was educated privately and at Christ Church, Oxford, graduating in 1882. He then entered University College Hospital, London, where he was Erichsen prizeman in operative surgery. He was, however, at heart an explorer, and for many years lived among primitive peoples. With the Micmacs of central Newfoundland, primitive tribes at that time still living mainly by hunting and fishing, he became proficient in woodcraft and learned to endure conditions which to the ordinary civilized individual would appear to border on privation. This early training served him to good purpose in his later travels, more especially during his stay among the Akikuyu of East Africa Colony, now Kenya, with whom he lived at a time when there was little exaggeration in terming them a 'prehistoric' people—the title he gave them in the valuable study of their manners and customs in "With a Prehistoric People" (1910), of which he was the joint author with his wife, Katherine, the daughter of the late Gurney Pease of Darlington, whom he married in 1906.

Mrs. Routledge, who had read history at Oxford, guided by the influence of Dr. R. R. Marett, was no less a keen anthropologist than her husband, and even while their joint book on the Kikuyu was in the making they were already planning their next and most important expedition. This was a journey to Easter Island to investigate and explore systematically the antiquities of that island, and more especially the origin and meaning of the sculptured statues and the script for which the island is famous, and of which the meaning had long been sought by travellers and anthropologists. The expedition, which sailed in a small schooner-rigged yacht with auxiliary power, named the *Mana*, which Routledge had built for the purpose, was in Easter Island when the War broke out in 1914. It returned to England in 1916, after visiting a number of islands in the Pacific, including Pitcairn, from which they brought back two descendants of Young, the mutineer officer of the Bounty, whom they presented to His Majesty King George V in an interview in July 1916. Further research on the history of Easter Island was carried out in 1920 and 1922, when the Routledges visited and surveyed the Austral and Gambier groups and collected much valuable anthropological material bearing on distribution. The results of the earlier expedition were published in a volume "The Mystery of Easter Island" which appeared in 1919.

WE regret to announce the following deaths:

Sir Edward Brown, former secretary of t National Poultry Council and first president of t World's Poultry Science Association, on August aged eighty-seven years.

Miss A. R. Clark, librarian at the Laboratory the Marine Biological Association of the Unit Kingdom at Plymouth.

Dr. Edmund Heller, director of the Fleishhack Zoological Park, formerly director of the Milwauk Zoological Gardens, on July 18, aged sixty-fo years.

Prof. L. Lévy-Bruhl, professor of philosophy the Sorbonne during 1899–1927, president of t Institut française d'Anthropologie during 1927–3 aged eighty-two years.

Dr. Heinrich Poll, formerly director of t Anatomical Institute, Hamburg, on June 12.

Prof. W. A. Tarr, professor of mineralogy a geology in the University of Missouri, on July 2 aged fifty-eight years.

NEWS AND VIEWS

Memorial to Sir William Perkin

IT was a pleasing thought of the people of Sudbury, now part of the new borough of Wembley, and of the friends of the late Sir William H. Perkin, to commemorate his long residence there by the erection of a memorial in the form of a tiny garden of rest and a large oval oak seat. The memorial was unveiled by the eldest Miss Perkin on August 12 in the presence of the civic authorities, the church, some friends and a large number of the public. An appropriate oration on Perkin's life and work was given by Dr. C. E. Goddard. The growth of London has swept away the peaceful home and garden and fields where Perkin retired to in 1874 to devote his life to research; he became also a good citizen and much beloved in the village. The memorial stands on a corner of his land, the noisy traffic thunders past it on two sides and there is a round-about in front. But this tiny spot is a haven of refuge and peace, and those who use it for a few moments in years to come can read the tablet and muse perhaps on what kind of a man was this Perkin, founder of the dye industry. 'Scientist and citizen' might appropriately have been added, for it was as the latter, a man conspicuous for his probity and good works, that Sudbury knew him.

Ship-Burial and Treasure Trove in Suffolk

THE verdict of the jury at the coroner's inquest, which took place on Aug. 14, on the Anglo-Saxon ship-burial, or rather on the grave furniture in precious metals found therein, at Sutton Hoo in Suffolk (see NATURE of August 5, p. 239), was such as, perhaps, might well have been expected. It would be more than difficult to argue convincing that a royal burial, in the circumstances indicat here by the character of the relics, could have tak place, with that secrecy and intention to resum possession, which have been laid down from time time in legal pronouncement as the essential princip of 'treasure trove'. Unless the matter is carri further in the High Court, as Mr. L. H. Vulliam, the coroner, indicated as a possibility, the Sutt Hoo treasure now becomes legally the property Mrs. E. M. Pretty, the owner of the land upon whi the burial was found by Mr. Guy Maynard of t Ipswich Museum. It may be hoped, however, th arrangements will be made in due course to ensu its display to the public and availability for stud as its historic interest demands. It would now appea since there has been an opportunity for the articl to be examined and cleaned in the British Museu that the find is far more valuable than was at fir reported. This is shown in the evidence of Mr. C. W Phillips of Selwyn College, Cambridge, who had bee in charge of the opening of the tumulus since Jul and also in a supplementary note contributed b *The Times* museum correspondent in the issue August 15 which mentions more especially the silve The objects in this metal include six shapely shallo bowls in almost perfect preservation, about 8 or inches across, and all provincial Byzantine or la Roman. They are decorated with a broad cros usually of a quatrefoil pattern. A silver dish decorat with a classical woman's head is provincial Byzanti work of the sixth century. A large platter, 28 inch across, was made at Constantinople, and bears mar of the reign of Anastasius I. The gold work, howeve a Saxon, and is said to be extremely massive. In association were forty Merovingian coins. It is thought that this may be the burial place of Redwald, the first of the East Anglian royal family to become High King of England.

The British Speleological Association

DR. R. R. MARETT's presidential address to the fourth annual Conference of the British Speleological Association, which met at Swansea on August 5–8, tendered in humorous vein an anthropologist's explanation of the attraction of the modern study of caves in 'speleolatry'—primeval man's worship of the cave, which in the racial consciousness of a late-born generation had assumed the guise of a devotion to science. He was, however, able to support his contention that speleolatry stood for something real in the history of religion by reference to the evident mystic intention, at least in part, of the palæolithic cave art of France and Spain and the therapeutic cult of the cave of later times. No doubt Dr. Marett had in mind the symbolism of a mystic ritual of approach, when at the opening of the Conference he presented Sir Cyril Fox, director of the National Museum of Wales, with a silver key. Members of the Association were given ample opportunity to experience the inward thrill of which their president had spoken, in the visits which were paid to the numerous caves on shore and inland in the neighbourhood of Swansea, in which the Paviland cave in the Gower Peninsula, famous in the annals of palæontology for its association with the name of Dean Buckland, received its due meed of attention; while in the exhibition arranged by Mrs. A. Williams at the Royal Institution of South Wales, they found illustration of the cave sites and their structure, as well as of the evidence of their occupation by men and animals, ranging from Mousterian to medieval times. Among those who addressed the Conference were Prof. T. Neville George, who discussed the geological aspect of the caves of South Wales, and Prof. Bosch-Gimpera, formerly rector of the University of Barcelona, who dealt with the cultures of the Spanish caves. Dr. Marett was re-elected president of the Association, with Prof. L. S. Palmer as chairman.

Totemic Ceremonial in Arnhem Land, Australia

DR. DONALD F. THOMSON, who was specially commissioned by the Government of the Commonwealth of Australia to investigate conditions among the aborigines of the Northern Territory during 1936–7, has collected much information relating to the customs and beliefs of the tribes of Arnhem Land, shown in numerous papers published in scientific periodicals and elsewhere since his return to England. He has obtained evidence, for example, running counter to the opinion, long generally accepted, that the indigenous peoples of Australia had been virtually free from external influence after their settlement there. It is now accepted, however, that influence from the north entered the continent at York Peninsula by way of Torres Strait; and Dr. Thomson finds in the use of wool or fabric to represent the hair of a dog in totemic ceremonial evidence of intercourse with early Malayan or Macassar voyagers, by whom this greatly valued material was brought to the area. Although the dog, which forms the central figure in a remarkable totemic ceremonial witnessed by Dr. Thomson and described by him (*Illustrated London News*, August 12), has been assimilated by the natives to the Australian dingo, it bears unmistakable evidence of an external origin, while the rites differ in many ways from the typical Australian totemic ceremonies. The ritual performance re-enacts in pantomime the myth of the original pair of 'dog' ancestors, who sank in the mud and were overwhelmed by the sea in trying to reach a stranded whale. Finally, they were turned into a great rock, whence now come the baby spirits of members of the clan who enter the mother at pregnancy. In the totemic ceremony, the figure of a dog, which has been constructed by the old men in secret, after giving birth to puppies—an event symbolized by cutting off the hindquarters—is carried along a road while members of the tribe imitate both the gait of puppies and the struggles of the original pair when caught in the mud. One of the tribal totems is a representation of a 'square-face' gin bottle carved in wood.

International Congress of Americanists in Mexico City

THE twenty-seventh International Congress of Americanists was held in Mexico City during August 5–15. General Cardenas was honorary president of the Congress, the acting president being Dr. Alfonso Caso, director of the National Institute of Archæology and History, whose excavations on Monte Alban have so greatly enriched the national collections of pre-Hispanic antiquities. Mr. T. A. Joyce, formerly of the Ethnographic Department of the British Museum, and Dr. Paul Rivet, of the Musée de l'Homme, Paris, and the foremost authority in France on the ancient indigenous peoples of America, were among those elected as vice-presidents for the meeting. According to a dispatch from the correspondent of *The Times* in the issue of August 8, 120 European and 180 Mexican and other American archæologists, anthropologists, and historians attended at the Congress. Communications were submitted in nine sections, which included anthropogeography, physical anthropology, American prehistory and archæology, as well as a section devoted specially to the prehistory and archæology of Mexico, linguistics, social anthropology and a section dealing with the practical problems which affect the indigenous and negro population of the continent. Excursions were made to archæological sites at Acolman, Teotihucan, Tenayuca, Tepotztlan, and the now famous Monte Alban.

Joint Industrial Councils

A BROADSHEET issued by Political and Economic Planning (P E P) reviews the present position of the joint industrial councils and their development from the Whitley Committee in 1916. During 1918–21, National Whitley Councils were established in 80 industries but afterwards a number of joint industrial councils collapsed or became moribund. By 1924 there were more than 30 trade boards and more than 50 Whitley Councils in existence but only three new national councils were set up between 1921 and 1930. Although the General Strike of 1926 emphasized the need for a more constructive relation between management and labour, and the Mond-Turner conferences assisted to break down old suspicions and frictions, the position between 1928 and 1934 was stationary. In the last few years, the basic ideas of industrial democracy, industrial organization and standing committees have gained support, and machinery for their implementation has been consolidated. Since 1933, new trade boards have been established in four industries, as well as a form of district organization, with statutory application of agreements, in road transport, while negotiations are proceeding for the improvement of conditions in retail trades by co-operative methods.

THE broadsheet describes in some detail the establishment, achievements and limitations of the two new Whitley Councils, the National Joint Industrial Council for the Clay Industries and the corresponding Council for the Cast Stone and Cast Concrete Products Industry. In addition the tendency in the older industries for standing committees representing employers and operatives and others, such as the Joint Committee of Cotton Trade Organisations, to be set up for many purposes is increasing. The building trades have set up the Civil Defence Constructional Industries Committee for the organization of demolition and rescue squads (both light and heavy) in the localities. A Joint Consultative Committee, representing the building employers, operatives and defence departments has also been set up to discuss defence problems affecting the industry. In flour milling there has been a joint deputation to the Government with proposals for maintaining supplies in war-time, while in the docks the employers and operatives are working out a scheme for the transfer of labour from port to port under emergency conditions in war-time. The driving force for co-operative effort no longer comes from a minority of enlightened employers and trade union leaders: on the workers' side particularly the impetus comes from the rank and file as well as from headquarters. Persistence of this attitude should lead to a new period of expansion in the organization of co-operation in British industry.

The Rockefeller Foundation

FIFTEEN million dollars were disbursed in 1938 by the Rockefeller Foundation for the advancement of "the well-being of mankind throughout the world". Being more than twice the year's income, this huge expenditure involved recourse to the principal fund as well as reducing accumulated balances. In addition to its complete annual report, the Foundation has published for wider circulation in pamphlet form an extraordinarily interesting review by its president, Raymond B. Fosdick. In the field of public health, in which alone the Foundation itself undertakes the conduct of operations, the fight against yellow feve progressed satisfactorily and more than a million vaccinations were performed with its new virus (17*D*). But a more formidable task is resistance to the invasion of South America by *Anopheles gambiae*, the most deadly of Africa's malaria carriers, introduce apparently by air traffic into Natal in Brazil nine years ago and steadily spreading westward. The Foundation is now co-operating with the Governmen of Brazil in organizing an anti-gambiae service. In all, 2½ million dollars were given to public health work. The account of contributions to work in the medical sciences is prefaced by a note on the comparative volumes, trends and merits of private and public support of medical-research in America and Europe and on the particular fields in which further research is likely to be most productive. One of the least developed is that of mental hygiene: "In no other field is the need more desperate or the potentialities for useful advances more promising. . . Cases of mental and nervous diseases occupy more hospital beds in this country than all other diseases combined."

WHILE medical sciences absorbed a quarter of the Foundation's 1938 appropriations (not counting 1,580,000 dollars given to the China Medical Board under an earlier authorization), an equal amount was spent in support of the social sciences, chiefly by financing a five-year programme of research and training in public administration in non-academic institutions. Believing that an understanding of the social forces moulding the future can only be arrived at through the dispassionate scientific approach which gave us command over our physical environment, the Foundation continued its support of various organizations working along such lines, notably the Institute of Pacific Relations and the Geneva Graduate Institute of International Studies. Of the 3 million dollars given to the natural sciences, more than half went to the University of Chicago for the endowment of biological research and more than a million in grants to other institutions for work in experimental biology. For projects of rural reconstruction in China 300,000 dollars were given, and despite Japanese depredations all these projects are still functioning. A sketch map shows the enforced transference towards the south-west of the scene of their operations.

Conditions and Aspects of the Scientific Profession

THE summer number of the *Scientific Worker* includes an account of an investigation of the profession of science which the Association of Scientific Workers is undertaking. The inquiry covers the methods of entry into the scientific profession and the actual conditions and economic aspects of the profession. The plan of research is designed to include a study of undergraduates in science departments and a study of practising qualified scientific workers. The former will endeavour to discover the factors which determine the decision to take a university course, the choice of university and course of studies and the extent to which vocational wishes influence these problems. The second will cover three groups of men of science—chemists, physicists and biologists—and will be directed to discover the objective conditions of scientific employment and the attitude of men of science to scientific training and employment. These studies will cover the training for and obtaining of scientific posts, the conditions of scientific employment as well as the tenure of posts and incidence of unemployment. The studies on attitude will embrace attitude to university, to employment and to the main types of professional associations. It is hoped that the results obtained will provide data upon which policy for the regulation of the scientific profession can be based and also indicate how the practice of science in industrial firms affects the development of industry as well as possibilities in the application of science to industry.

Education in Germany

THE main features of education in Germany as remoulded under the Nazi regime are presented in a bulletin ("Education in Germany". Washington, D.C.: Government Printing Office, 1939) prepared for the United States Office of Education by Dr. Alina Lindegren, specialist in west European education, who visited Germany in 1935 and 1936 and completed her investigation of the subject a year ago. Among the most pregnant changes have been those in the education of teachers. Long before the Nazi party came into power its leaders resolved on a rapid unification of the teaching staffs and on eliminating teachers antagonistic to its views. The resultant limitation and precise definition of objectives must have been important factors in the production of a vigorous and efficient system. For teaching in elementary schools, candidates must enter two-year training colleges in which the curriculum includes three main fields: political world-view (*weltanschauliche*) education, scientific study and practical work. Entrance conditions include ability to sing and to play the violin, piano or organ and to instruct in gymnastics and sports. Women must in addition qualify in needlework and home economics. Aspirants to secondary school teaching posts must spend a year in one of these training colleges so as to mix with candidates for elementary school-teaching and so help to unify the profession. The declared purpose of the secondary school is to give preliminary training to especially gifted young people fit to qualify themselves eventually for authoritative positions in the political, cultural and economic life of the nation, and "the constant basis of selection shall be physical fitness, fitness as to character, mental fitness or ability, and national fitness". Conditions of study in the universities, which are subject to close control by the Reich Government, are elucidated by a comparison with the corresponding conditions in the United States.

Educational Finance in the U.S.A.

IT has long been recognized in the United States that there are glaring inequalities between the educational opportunities available in different parts of the country and that the systems of financing the public schools do not take sufficient account of the distribution of financial resources. The resources of many States being insufficient for remedying these inequalities, Federal aid has been invoked again and again in the past five-and-twenty years to correct defects in particular fields—first vocational education and later rural education, teacher training, health work in schools, nursery schools and adult education—but hitherto there has been no comprehensive measure for making good the radical defects in the systems of financing the public schools. The President's Advisory Committee on Education, constituted in 1936, with special reference in the first instance to vocational education, has lately taken this matter in hand, and a pamphlet on "Principles and Methods of Distributing Federal Aid for Education" has been prepared by its research staff (Supt. of Documents, Washington, D.C. 20 cents). It starts with the assumption, based on a study of present costs, that 48 dollars per pupil per annum is not more than enough to pay for elementary and secondary education of tolerable quality in a community enjoying optimum conditions of cost and is insufficient where sparsity of the population or high cost of living enhance the expensiveness of education. It proceeds to elaborate ingenious plans for distributing Federal aid, amounting to upwards of 600 million dollars a year, designed to approximate to the ideal—to each community according to its educational needs, from each according to its means.

Association for the Study of Systematics

THE Association for the Study of Systematics in Relation to General Biology was formed in 1937 (see NATURE, 141, 163; 1937: 142, 1069; 1938). Up to the present, the organization of the Association has been deliberately kept as loose as possible, and there has been no subscription. In a leaflet recently issued it is announced that the annual subscription is now five shillings. Further, a fund has been started to provide for expenditure on special purposes. Donors of £5 or more to this fund during the next three years will be designated founder members, and will enjoy for life the privileges of ordinary members. The leaflet also outlines the work so far carried out by the Association. It is hoped that all present members will continue on the new terms and that other biologists will find themselves in sympathy with the aims of the Association. Copies of the leaflet, with forms of application for membership, can be obtained from Mr. H. W. Parker, British Museum (Natural History), Cromwell Road, or from Mr. J. S. L. Gilmour, Royal Botanic Gardens, Kew, Surrey.

Blood Group Tables

THE rapid increase in the literature on blood groups makes it desirable to have a reference work on the subject. Dr. William C. Boyd has supplied this need (*Tabulæ Biologicæ*, 17, 113–240) by presenting the basic facts in tabular form with a minimal amount of text. All the essential facts regarding blood groups are given, together with nearly 500 references to the literature. Part 1 is general, its nine sections including tabular treatment of the chemical and serological nature of the agglutinogens *A*, *B*, *M* and *N*; relations to other species; subgroups; heredity of the types; medico-legal applications; relation to disease; and blood groups in animals. Part 2 is anthropological, giving maps of the world distribution of the *A* and *B* and complete tables of the frequency of *A* and *B* as well as *M* and *N* in the various ethnic stocks tested in all parts of the world up to the time of publication. By the use of two kinds of type an attempt is made to distinguish between the more reliable results and those which, because of small numbers (less than 200) or for other reasons, are regarded as less reliable. This compilation of the serological and anthropological facts regarding the blood groups will be of much service to all workers who are interested in this subject.

Position of the Illegitimate Child

THE League of Nations has just published a "Study on the Legal Position of the Illegitimate Child" (London: George Allen and Unwin, Ltd., 1939. 4*s*.). The study opens with a short historical survey of the social aspects of the legislation on the subject in various countries, followed by an analysis of the various legislative provisions respecting civil status, name, nationality and legal domicile, and inheritance rights. The fate of the illegitimate child being closely bound up with that of its mother, a chapter on the unmarried mother's rights is included. The last part of the volume deals with social insurance laws, and welfare measures, including public assistance and preventive health measures.

Television Broadcasting

SIR NOËL ASHBRIDGE gives a review of the progress being made in broadcasting and television in the *Proceedings* of the Wireless Section of the Institution of Electrical Engineers of June. The period under review extends from the end of 1934 until the end of 1938. During this period the number of licence-holders in European countries has increased by more than 60 per cent. The details of the Royal tour in America in increasing the popularity of sound broadcasting have not yet been published, but it is known that the excellent broadcasts of sound and television have greatly increased the popularity of the British Broadcasting Company. The second part of Sir Noel's report deals exclusively with television broadcasting. The great improvements made in the quality of the pictures shown, the great trouble taken by the Government Post Office to locate the position and find out the cause of the interference, when complaints are made, and the remedies they suggest, in many cases completely eliminating the trouble, have satisfied the users in nearly every district. The nominal hours of transmission are now from 3 to 4 p.m.; and from 9 to 10 p.m. The vision transmitter and the studio and control room equipment at the Alexandra Palace Station have been considerably improved; in particular, an improved type of 'Emitron' tube, known as the long-gun type is now in use for studio work. It is now possible to obtain very satisfactory results with telephoto lenses Satisfactory reception is possible up to a radius o about thirty miles from the Palace. In exceptiona cases reception has been reported up to 200 miles It is hoped that in the future international standardization with regard to definition and picture frequency may become available, as the absence of a commo standard would be a most serious drawback.

A Factory without Windows

A DESCRIPTION is given in the *Electrical Review* o August 4 of a factory without any windows whic is being constructed for the Simonds Saw and Stee Co. at Fitchburg, Mass., U.S.A. It is completely air-conditioned and artificially illuminated throughout. It concentrates productive machinery now covering 17½ acres in several plants, into 5½ acre of production space, from which daylight is completely excluded. Lighting fixtures are being installed in 1,440 positions. Each consists of a 100-watt lamp and a simple curved porcelain reflector. These produce an illumination of not less than 20 ft. candles throughout each room on the working plane The Company plans to operate the new plant intensively on a three-shift basis, so that the work goes on continuously day and night. Service main for water, gas, steam, power, light, air and oil are laid between the floors through ducts direct to more than 1,000 machines and furnace positions. The plant has a connected power load of 6,000 horsepower and a total of 4,200 electric outlets giving current for light, machine power, transformers, motor-generators and other units. Dust and exhaust gases are removed through underground ducts, served by thirty dust-removal units. The entire building is air-conditioned by Carrier units and the humidity and temperature controlled through hydrostats and thermostats at four special positions. 'Man-cooler' systems have been provided for the comfort of men working at the furnaces. Air will be circulated through the building at the rate of about 400,000 cub. ft. per minute. It enters the structure through louvres on the end walls of four lean-to buildings which adjoin the main building. Water is obtained from four artesian wells by electric pumping. Air is blown through water-sprays in each of these structures before being distributed.

The All-Welded Hull of H.M.S. *Seagull*

H.M.S. *Seagull* is one of the two minesweepers ordered to be built at Devonport Dockyard as part of the 1936 Naval programme. It was decided that *Seagull* should be built all-welded, whilst the sister ship *Leda* should be constructed in accordance with the normal practice, that is, mainly riveted. The occasion was to be utilized by obtaining a trustworthy comparison between the two methods of construction. So far as was practicable, the thicknesses of plating were left unaltered. The *Seagull* was launched on October 28, 1937, the launching weight as 313 tons, and the weight of the *Leda* was 338 ons. The welded vessel was commissioned and ompleted in 1938. Both ships underwent rough- eather trials in Faroe–Icelandic waters for about fortnight in September 1938.

A PAPER read by A. Nicholls on the *Seagull* to he Institution of Naval Architects on March 31, 939, and abstracted in *Electric Welding* of June, ives the conclusions to be deduced from the relative osts of building the two ships and their behaviour hen on active service. In the discussion on the paper, he Captain of the *Seagull*, who was present, said hat he had found the vessel perfectly satisfactory in ll respects, although he admitted that he had his oubts when he heard that he had been drafted to n all-welded ship. He had taken her to the region f Iceland for her trials in order to give the vessel a evere test in rough weather, and he testified to the lmost complete absence of creaks and groans. He had ound that at the same revolutions per min. his vessel as faster than any other in the flotilla, due, he hought, to the saving in weight, and he found that er fuel consumption was considerably less than the *eda* and the other vessels of the flotilla. On the *eagull*, which was a minesweeper, there was very ttle vibration from the winch aft, when drawing n the cables. The author concluded that there are o insuperable difficulties in the way of fabricating ship's structure entirely by welding and that the edistribution of labour entailed by the new technique oes not involve additional expense nor increase the ime of building.

ew York and London Roads

IT is stated in *Roads and Road Construction* of uly that municipal engineers were greatly impressed y the highways followed during the Royal tour in he environments of New York. In particular the est Side Express Highway, the Triborough Bridge, he Henry Hudson Parkway and the Great Central arkway can be described as magnificent highways. hey form part of the system which has been built p during the past ten years near New York. Some f the engineers have returned with plans for bringing ertain old-fashioned highways of Great Britain up o date. In New York City and Long Island alone here are more than a hundred miles of parkway and early two hundred fly-over crossings. Traffic using hese routes is able to reach the heart of Manhattan ithout a single hold up such as those which delay otorists many times on most routes into big cities f Great Britain. The question is discussed why ew York and in a lesser degree Paris, Rome and erlin have been able to achieve what London has nly been able to do in a very minor degree. It is uggested that there are two factors, the first connected with organization and the second with a appy choice of opportunities and times for road uilding. The development of parkways in the icinity of New York was conceived and promoted y an independent organization known as the Long land State Park Commission. This Commission as pursued a continuous policy, and has overcome difficulties in a way impossible to a well-meaning local authority. The opportunity presented by the economic crisis of 1929 and the vast sums afterwards distributed by the Federal Government for the relief of distress and unemployment was taken full advantage of with very happy results. The result has been that New York has now an unrivalled arterial road system. It is hoped that a similar coincidence, namely a strong independent planning authority aided by the central government could, and perhaps one day will, do the same for London.

A 'Hot' Lightning Flash

A RECENT report issued by Science Service, of Washington, D.C., states that the Westinghouse Company has perfected a method, first discovered by P. L. Bellaschi, for producing an artificial electric discharge which imitates natural lightning in its ability to set fire to materials in its path. This form of discharge, which is called 'hot' lightning, is used for the routine testing of all high-tension power transformers sent out by the Company. The volt-amperes required for the test are 1½ million volts, 80,000 amperes. In the previous method used of creating discharge flashes, the heat developed was intense and they had enormously destructive explosive effects on whatever they hit unless it was adequately protected, but they did not last long enough to set fire to combustible targets, only leaving a scorched hole. In the 'hot' lightning stroke, there is a low-amperage, long-duration stroke following the main and 'leader' lightning discharged, similar to natural lightning. The after-stroke of 'hot' lightning generates temperatures only half as high as the main stroke, but it lasts between 100 and 1,000 times as long. The long-duration charge is produced by means of additional condensers or by a transformer from which the charge is 'soaked' through a series of resistance inductance coils in oil and permitted to follow the initial high-current discharge relatively slowly. Demonstrations are shown by the Company of 'hot' lightning, fusing sand in a fibre tube, setting fire to cotton cloth and burning holes through copper sheets varying from one thirty-second to one-sixteenth of an inch in thickness.

Earthquakes during May 1939

ACCORDING to the Bureau central séismologique de Strasbourg, 120 earthquakes were felt by people or recorded by instruments during May 1939. Eight were registered on each of the first and last days, seven were registered on each of the sixth and fourteenth, and only one was registered on each of the seventh, fifteenth, eighteenth and twenty-ninth. The most severe shocks appear to have been those in the region of Akita, Japan, on the first, in California near 29·5° N., 113·8° W. on the second, in the Azores (scale 5 on the island of Santa Maria) on the eighth, in the monts d'Aubrac, France (scale 5) on the sixteenth, in the Adriatic on the twentieth, and at Kalacryta (Greece) where houses were cracked and the intensity reached 8 on the Rossi-Forel scale on the thirty-first, six in all. The last of these appears to have been the most intense. It was accompanied by a great noise and was followed by twenty-seven aftershocks, seven of which were strong. Next in order of intensity were those of the sixth, felt scale 4 at Calapan in the Philippines, the seventeenth with epicentre in the Pacific south of the Bonin Islands, the eighteenth felt scale 4 at Brig in the Jura bernoise, Switzerland, and the twenty-seventh at Birmanie near 25° N., 95° E. The moderately strong seismic activity in Italy appears to have been continued, shocks having been experienced during May near Romagna, Bologna, Pouilles and Isernia.

International Conference on Flames and Furnaces

An International Conference on Flames and Furnaces will be held during September 17–20, 1940, at the Royal Institution in London on the initiative of the Institute of Fuel and the British Coal Utilisation Research Association. One purpose of the Conference is to bring the new developments of chemical kinetics and spectroscopy to the notice of engineers and industrialists with the view of accelerating their practical application. The technical programme of the International Conference in 1940 has been prepared by a Committee of thirty engineers and scientific workers. Flames in the internal combustion engine and explosive flames generally are excluded from the scope of the Conference, which will be concerned with the free combustion of gases, liquids and solids in air. The Editorial Committee proposes to invite the authors of papers to collaborate in covering the whole ground of flame and furnace research with the minimum of overlap. Selected authors throughout the world will be asked to contribute papers on specified problems, and early in 1940 the Editorial Committee will co-ordinate the various papers with the help of selected experts in each field acting as chairmen and reporters of the various technical sessions. It is hoped to secure a large attendance of foreign engineers and scientific workers for a conference which should have great practical industrial significance.

International Genetical Congress

The programme of the seventh International Genetical Congress to be held in Edinburgh during August 22–30 has now been published. Pre-Congress activities include an International Conference on Nomenclature and Terminology of Cytology and Genetics, organized by the International Union of Biological Sciences and the Institut International de Co-operation Intellectuelle, to be held in London during August 14–17. A tour has also been arranged to cover London, Cambridge, Chester and Windermere. During this tour, various institutes at Cambridge will be visited on August 18 and 19, and the Fresh Water Biological Station at Wray Castle, Windermere, will be visited on August 22. Full details of the Genetical Congress to follow at Edinburgh are given in the programme, a copy of which can be obtained from Prof. F. A. E. Crew, Institute of Animal Genetics, King's Buildings, West Mains Road, Edinburgh.

Announcements

The Clement Cleveland Medal has recently bee awarded to Mlle. Eve Curie by the New York Cance Committee in recognition of her biography of he mother. This is the first time that this distinctio has been conferred upon a foreigner.

Dr. Eugen Fischer, professor of anthropology i the University of Berlin, has been awarded th Goethe prize for art and science by the Germa Chancellor.

The following appointments and promotions in th Colonial Service have recently been made: S. Barnett, veterinary officer, Kenya; W. J. Gra veterinary officer, Tanganyika Territory; F. Waddington, veterinary officer, Tanganyika Terr tory; H. T. Dale, meteorological assistant, Nigeria W. H. C. Belgrave, chief research officer, director agriculture, Straits Settlements, and adviser agriculture, Malay States; A. C. Shill, adviser agricultural marketing and controller of agriculture exports, Malta, chief horticultural officer, Palestine T. A. Strong, conservator, Malayan Forest Servic conservator of forests, Ceylon.

The thirty-first annual Autumn Meeting of th Institute of Metals will be held in Glasgow durin September 5–8. Further information can be obtaine from the Secretary, Iron and Steel Institute, Grosvenor Gardens, London, S.W.1.

The Association of Special Libraries and Information Bureau (ASLIB) will hold its sixteenth annua Conference at University College, Nottingham, durin September 15–18, under the presidency of Sir Harr Lindsay. Further information can be obtained fro the General Secretary, Association of Speci Libraries and Information Bureaux, 31 Museu Street, London, W.C.1.

The Swiss Society of Naturalists will hold its on hundred and twentieth meeting at Locarno durin September 23–25 in conjunction with the Swis Medico-Biological Society. The subject for discussio will be the pathology and clinical aspects of hereditar diseases and their diffusion. Further information ca be obtained from the secretary, Prof. E. Ludwig Pestalozzistrasse 20, Basel.

The eighth Congress of the Institut Internation d'Anthropologie will meet at Istanbul during September 18–25 under the presidency of Prof. E Pittard of Geneva, president of the Institute. Th meeting will be held in five sections, coverin palæontology and archæology, physical anthropolog heredity and blood groups, social anthropology linguistics and the history of religions.

The Rockefeller Foundation has established training fellowship in psychosomatic research tenabl at the Tavistock Clinic, of the annual value of £45 available for three years from September 1, 193 Further information may be obtained from D A. T. M. Wilson, Tavistock Clinic, Malet Place, W.C.

LETTERS TO THE EDITORS

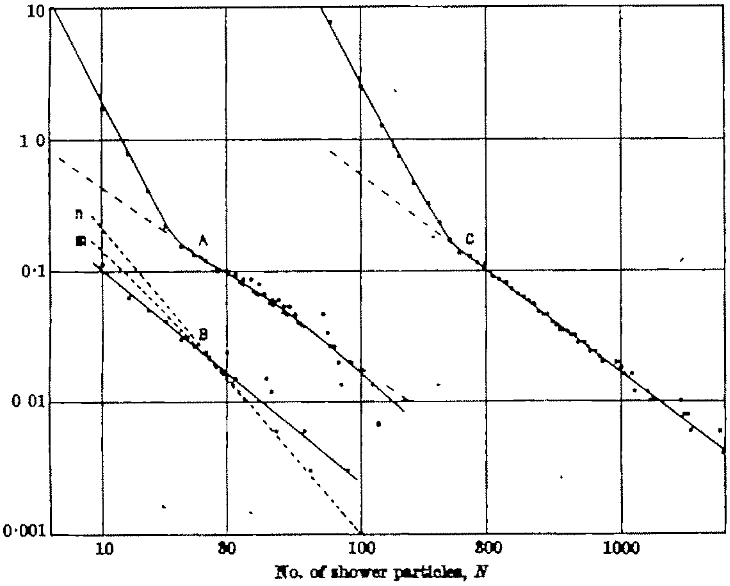
The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 334.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Cosmic Ray Ionization Bursts

COSMIC ray ionization bursts produced by showers f ten or more particles in a small ionization chamber volume 1 litre) have been recorded at sea-level in ambridge and, thanks to the hospitality of Prof. . M. S. Blackett and Dr. H. J. J. Braddick, under 0 m. of clay in London. The data discussed here, urves *A* (150 hours) and *B* (350 hours), are from ms with no lead or other dense shower-producing aterial above the chamber (the wall of the chamber as of duralumin, 1·2 cm. thick, so as to avoid much as possible showers produced by cascade ultiplication in the chamber itself). Curve *C* 00 hours) is the result of similar observations sea-level with a large ionization chamber (volume 5 litres, wall-thickness 0·3 cm. of steel), most of hich were published by one of us[1] in 1936, when e method of recording was also described. The urves show the number of showers per hour in hich *N* or more particles intersected the ionization amber; the number of shower particles *N* was timated on the basis of a specific ionization in rmal argon of 90 ion-pairs per cm.



The ionization bursts obtained at sea-level with the g ionization chamber (curve *C*) involve much larger mbers of shower particles than those obtained with e small chamber (curve *A*), and also each curve s a remarkable change of slope at a rate of currence about 0·16 per hour. The curves, hower, can be superposed fairly closely if the size of e showers in the small chamber is multiplied by . We deduce from this approximate proportionality the *size* of these showers (as distinct from their te of occurrence) to the areas of the thin-walled chambers used to observe them that they are mostly *extensive showers*, originating in the atmosphere, of the same type as those found by Auger and his co-workers[2] with counters. We should not expect to find exactly the ratio of the areas (approximately 1 : 30) because narrow showers or condensations of rays of cross-section smaller than the area of the large chamber tend to increase disproportionately the bursts in the small chamber.

The bursts which are found underground (curve *B*) must be produced by the penetrating component of the cosmic rays. We have calculated the distribution curve to be expected in the tube station for cascade showers produced by electrons 'knocked on' by mesons using the data given in the paper by Bhabha[4] in which, however, the meson was assumed to have spin ½. We adopted, following Euler and Heisenberg[5], an exponent 1·87 for the integral energy distribution of the mesons originating in the atmosphere. The calculation shows (curve *m*) that the showers resulting from this process alone are nearly sufficient to account for the bursts recorded underground, if we assume that the cross-sectional area of the showers underground is not much greater than the area of the chamber (actually more of the larger bursts are found than are given by this calculation, but the theoretical implications of this discrepancy will be discussed later).

At sea-level a similar calculation (curve *n*) gives much fewer bursts than are observed even if we suppose that the showers are so narrow that all the shower particles in any one burst can intersect the small chamber: but we already know that most of the showers observed at sea-level are at least wider than the large chamber. We therefore conclude that a negligible number of the extensive showers observed at sea-level is produced by electrons knocked-on by mesons. It would seem also that an insufficient number of such showers can be produced by the spontaneous decay of the meson, a process which might be invoked to explain the steeper parts of the sea-level curves.

We think, therefore, that nearly all the showers which produce bursts at sea-level in our thin-walled ionization chambers originate very high in the atmosphere, and that the dual nature of the distribution curve at sea-level (as indicated by the change of slope) is due, not to the existence of showers of two kinds, but to the fact (already noted by Auger[2]) that each extensive shower has a core of closely spaced particles surrounded by a relatively wide fringe of much more thinly spaced particles able to produce bursts of small size.

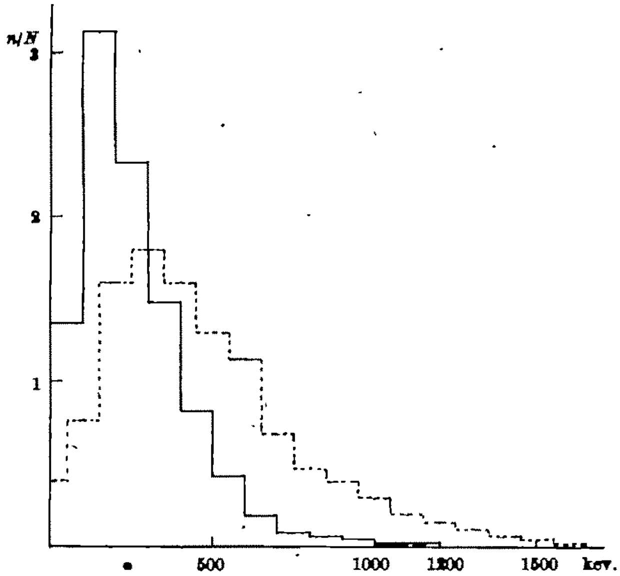
β Spectrum of Actinium K

THE radio-element actinium K recently discovered[1] derives from actinium ($Z = 89$) by emission of an α-particle and is placed in the position 87 of the Mendeléeff table. This element behaves chemically like an alkaline metal, and its period is 21 minutes.



β-Continuous spectrum of actinium K (full line) and of actinium C″ (dotted line).

Actinium K has been prepared from an aqueous suspension of lanthanum fluoride containing actinium. The different radio-elements normally deriving from actinium were eliminated by eight successive precipitations of carbonates (lead, barium, lanthanum) with ammonium carbonate. The residual solution was evaporated and calcined. The decay curve of the product obtained by this way shows that the actinium K is radioactively pure.

A fraction of the product was placed on a sheet of mica 20 μ thick or on a sheet of aluminium 5 μ thick and introduced into a Wilson cloud chamber. The method of introduction of the sources and the method of measurement of the β-ray tracks have already been described[2]. 1,600 β-rays have been measured in this way, and the continuous spectrum obtained is represented in the accompanying graph. For comparison the continuous spectrum of actinium C″ has been indicated in the same figure.

The principal characteristics of the spectrum are brought together in the following table, in which are also shown the characteristics of the continuo spectra of actinium B and actinium C″.

	E_p (kev.)	E_m (kev.)	E_M (kev.)
Actinium K	150	265	1·200
Actinium C″	300	470	1·600
Actinium B	400	360	1·000

E_p = energy corresponding to the maximum probability emission.
E_m = average energy.
E_M = maxima energy.

There have been observed on the photograph plates tracks of a certain number of positons th energies of which vary from 400 to 2,000 kev. Th frequency of these positons is ten times higher wh the mica sheets are used instead of the aluminiu It is thus possible that the actinium K emits an inten γ-radiation of more than 3,000 kev.; the posito observed would result from the materialization these γ-rays in the support.

If we admit that the upper limit of energy actinium K spectrum is 1,200 kev. this point is fou on the upper branch of the Sargent curve, correspon ing to permitted transitions.

Phase Transitions of Nuclear Matter

THE distribution of capture cross-sections of slo neutrons reveals a surprising concentration strongly absorbing elements in the region of t rare earths[1]. As has been pointed out[2], this fa may be explained in the simplest way by the su position that the mean spacings between th resonance capture levels of slow neutrons have minimum in this region of the periodic system. more detailed study of the connexion between th distribution of the capture cross-sections and th variation of resonance level density carried out me seems to prove definitely the non-monoton shift of the resonance level spacings with a minimu in the region of the rare earths (mean atomic weig 160).

This fundamental fact permits us to draw so conclusions on the properties of excited nucle matter. The general conception of nuclear excitati due to Bohr[3] enables us to treat excited nuclei thermodynamical systems. Between the mean lev spacing D and the thermodynamical quantities the nucleus, we have the relation[4]

$$D \sim e^{-S(E,A)}, \qquad (1)$$

where S is the entropy of the nucleus as a functi of the excitation energy E and the atomic weight From (1) it follows that a minimum of D implies maximum of S if all thermodynamical quantities a assumed to be continuous. Consequently the nucle entropy at excitations equal to the dissociati energy of a neutron Q varies non-monotonicly wi A. As is well known, Q is fairly constant for lig elements but decreases slowly towards the end the periodic system because of the coulomb repulsio If all the nuclei at excitations equal to Q were in t same thermodynamical state, then the excitati nergy should be given as a function of the nuclear emperature Θ by a common expression of the form

$$E = \alpha \cdot \Theta^n. \qquad (2)$$

According to Landau and Weisskopf, $\alpha \cong \alpha_0 \cdot A$ and $n = 2$, while according to Bethe $\alpha = \beta \cdot A^{2/3}$ and $n = {}^7/_3$. It may be shown quite generally that here does not exist any power dependance of E upon Θ which agrees with the non-monotonic variation of D exhibiting a sharp minimum at $A = 160$, at any rate if we assume $\alpha \sim A$ or $\alpha \sim A^{2/3}$. Thus the shift of D shows, either (I) that not all nuclei are in the same thermodynamical state at excitations equal to Q, which excitations for the heavier nuclei correspond to lower temperatures, or (II) that the coefficient α in equation (2) is a complicated and possibly non-monotonic function of A, due perhaps to the variation with A of the relative effects of the electrical and short-range nuclear forces.

The first possibility, which seems to us to be the more likely one, means that the properties of excited nuclear matter change at a certain temperature. So we arrive at the *hypothesis of phase transitions of nuclear matter*. This hypothesis is especially attractive since it makes nuclear matter analogous to two other quantum 'liquids', namely liquid helium and the conductivity electrons which also undergo phase transitions at low temperatures. Perhaps phase transitions are a common property of any liquid exhibiting sharply expressed quantum properties, but only the further experimental study of the structure of the nuclear energy spectrum can ascertain whether nuclear matter really exists in two different phase modifications.

The same hypothesis of phase transitions has also been suggested simultaneously by Dr. I. Pomeranchuk. A more detailed discussion of the problem will be published in a paper to appear in the *Physical Review*.

Effect of Tube-Length on the Visibility of Dust Particles with an Oil-immersion Objective

WHEN a well-corrected oil-immersion objective is used to examine dust particles mounted in a medium such as Canada balsam, of similar refractive index to the oil, the finer particles will give a very similar image on either side of the correct focus, provided the objective is used at the tube-length for which it is designed. We have found, however, that if the dust deposit is mounted dry on the underside of the microscope cover-glass, the image on either side of the correct focus is not the same at the specified tube-length, and in order to obtain the best images, the tube-length must be reduced.

The dust deposits which are collected on a cover-glass by the thermal precipitator are mounted dry in the above way, and examined with a 2-mm. apochromatic oil-immersion objective, *N.A.* 1·30. In these circumstances a considerable fraction of the finest particles are not visible unless the tube-length is reduced until the images on either side of the focus are similar. The necessary reduction in tube-length is of the order of 2 or 3 cm., an amount which is often beyond the tube-length adjustment of an ordinary microscope. An equally satisfactory correction can, however, be obtained by using the adjustable tube-length corrector designed by the British Scientific Instrument Research Association, at the tube-length specified for the objective.

The details of this investigation and of certain other factors which affect the counting of dust particles will be published elsewhere.

We wish to thank the Gold Producers Committee for permission to publish this communication.

Electronic Conduction of Magnetite (Fe_3O_4) and its Transition Point at Low Temperatures

WE have measured the electronic conductivity, down to liquid nitrogen temperature, of a number of iron oxides of the homogeneous 'Fe_3O_4' phase, especially as a function of the exact stoichiometric composition of the material. This seemed of theoretical interest for several reasons:

(*a*) Fe_3O_4 is an abnormally good conductor among the semi-conductors with partially filled lattice bands[1].

(*b*) Fe_3O_4 has a very remarkable crystal structure involving a probably statistical distribution of both Fe^{2+} and Fe^{3+} ions at equivalent lattice points[1].

(*c*) There are indications that Fe_3O_4 shows a transition point in the neighbourhood of 120° K. Anomalies in the magnetic behaviour[2] at 120° K., in the specific heat[3] and in the lattice constant[4] at 114° K., have been found. The magnetic anomaly, however, depends on the mode of preparation[5].

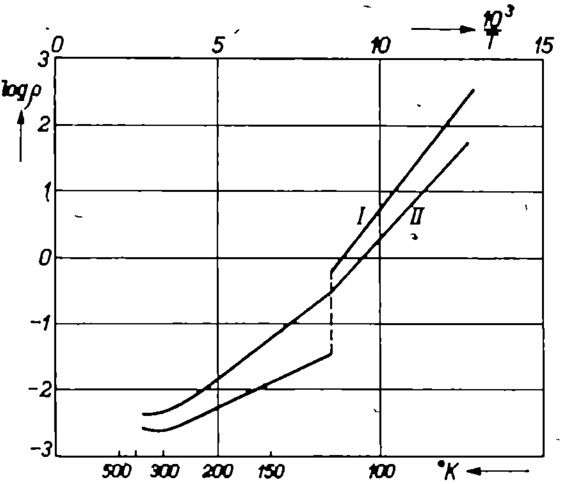
We thought it possible that the statistical distribution of Fe^{2+} and Fe^{3+}, which is a statistical distribution of electrons about the double number of lattice points containing Fe^{3+}, and which accounts for the rather high electronic conductivity of magnetite, would lead to some type of order at lower temperatures. A transition of this kind would probably offer an explanation of the anomalies at 120° K. One would expect such a transition to be very sensitive to the ratio Fe : O in the crystal, since an excess of oxygen (solid solutions of Fe_3O_4 and γ-Fe_2O_3) would imply: (*a*) vacant lattice points in the 16-fold position[6] containing, in stoichiometrically pure Fe_3O_4, 8 Fe^{++} + 8 Fe^{+++}, and (*b*) an increase of the ratio $Fe^{3+} : Fe^{2+}$ at this lattice position; both factors would be unfavourable with respect to order. For the irregularities found by Hilpert and Forrer this would supply an explanation more satisfactory than that put forward by these authors.

Furthermore, one would expect that such a transition, involving the conducting electrons, would be accompanied by very pronounced effects in the specific resistance at the transition temperature.

Actually we have found a strong discontinuity in the resistivity curves of some Fe_3O_4 samples, and a considerable influence of the ratio Fe : O.

The main difficulty consists in the preparation of homogeneous crystalline samples of varying composition but all belonging to the Fe_3O_4 or magnetite (spinel) phase[7]. Details of our present technique will be given elsewhere; we used pure oxide pressed into bars and sintered at about 1,300°.

We have found for magnetite with a composition in the neighbourhood of Fe_3O_4 a gradual increase of the resistance (for example, by a factor 10) as one goes from 300° K. to 120° K., a sudden increase of the resistance at approximately 117° K. by a factor of the order 100, and towards still lower temperatures again a continuous increase. Samples containing an excess of Fe_2O_3 in solid solution, however, show a stronger gradual increase of the resistance with decreasing temperature, but a much smaller jump in the curve at about 120° K. or even merely a change in the temperature coefficient of the resistance in that temperature region.



The accompanying graph shows log ρ against $1/T$ for two bars: I with $FeO : Fe_3O_4 = 1 : 1{\cdot}025$, and II with $FeO : Fe_3O_4 = 1 : 1{\cdot}08$. All details of the curves are in full accordance with the picture proposed above for the nature of the transition and our concept of the cation arrangement in the Fe_3O_4 (and the γ-Fe_2O_3) lattice. In further support of our views, we found that sample I shows a distinct drop in the susceptibility for weak magnetic fields at about 117° K., whereas with sample II the corresponding effect is much weaker.

A more complete account of this work, and details about certain hysteresis phenomena accompanying the transition, will be given elsewhere. Measurements at liquid hydrogen and liquid helium temperatures are in preparation.

New Iodine and Fluorine Derivatives of Monosilan

WE have recently investigated the reaction betwee monosilane, SiH_4, and hydrogen iodide at 80° i the presence of aluminium iodide, and have isolate from the products two stable iodides of the formul SiH_2I_2 and SiH_3I, which are formed together wit silico-iodoform and silicon tetraiodide. The forme is a heavy colourless liquid of low volatility (vapou pressure 2–3 mm. at 0°), while the monoiodid is a liquid of boiling point 45·8° and meltin point −56·5°, which resembles methyl iodide i appearance.

Both these compounds attack mercury, and, in th case of silyl iodide, the products have been shown t consist of monosilane, disilane, hydrogen and me curous iodide. It is possible that mercury sil iodide, $HgSiH_3I$, might be formed under certai conditions, but this compound is certainly less stabl than mercury methyl iodide. Silyl iodide in the vapou phase absorbs light of wave-length less than abou 2800 A. and is rapidly decomposed by light in presenc of oxygen, with liberation of free iodine. Both iodide burn readily in air, with liberation of free iodine an formation of silica.

Silyl iodide reacts with magnesium in the presenc of anhydrous ether. Some magnesium is dissolve and the residue is blackened. At the same time white, ether-soluble compound separates in smal amounts and hydrogen and monosilane are evolved Addition of water results in the evolution of furthe quantities of hydrogen and monosilane. It is though that this reaction is due to the formation of a Grignar compound by the silyl iodide. Its stability is evidentl lower than that of the corresponding compound pre pared from methyl iodide. The numerous syntheti reactions which a compound of the above typ would be expected to undergo are being furthe investigated.

The reaction between dichlorosilane and antimon trifluoride at room temperature, in presence of anti mony pentachloride as catalyst, has yielded a ne fluorinated silane of the formula SiH_2F_2 (boilin point, − 77·5°; melting point, − 119·1°). Thi substance is separated with difficulty from silico tetrafluoride, which is also formed in the reactio by a process of fractional condensation at low tem peratures. The fluoride is an inflammable gas whic is without action on mercury or glass. Silyl chlorid SiH_3Cl, undergoes a similar reaction with antimon trifluoride, but the products have not yet been com pletely separated.

Anomalous Thermal Expansion of Carbon Disulphide at Low Temperatures

APPLYING the method of Kamerlingh Onnes an I. A. D. Boks[1] and using special quartz apparatu I have determined the value of the ratio v_t/v_0 fo carbon disulphide in the domain of temperature from + 20° to − 112° C., giving particular attentio to the vicinity of − 80°, because at temperature lower than that the carbon disulphide become nuddy, small quantities of sulphur floating in the iquid.

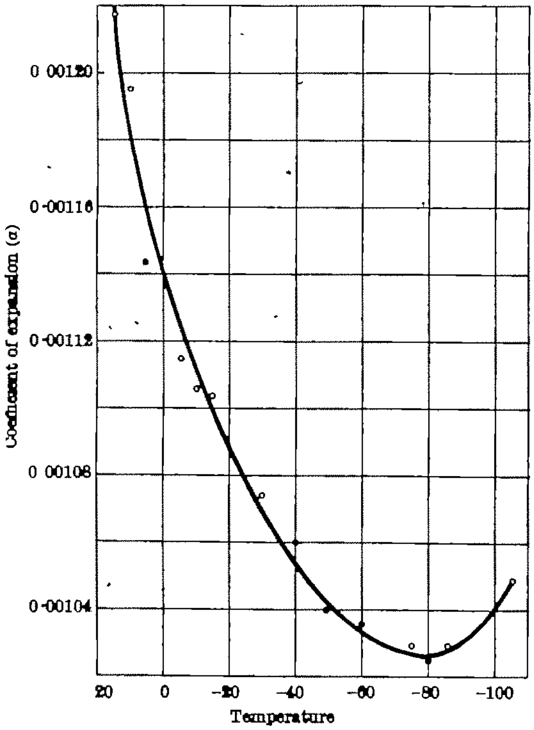
On the basis of these experimental results, I have alculated the coefficient of expansion

$$\alpha = \frac{1}{v}\frac{dv}{dt},$$

and also the variation of this coefficient with temerature, namely, $\frac{1}{\alpha}\frac{d\alpha}{dt}$ for the whole domain investigated. It appears that the coefficient of thermal xpansion of carbon disulphide decreases rapidly with temperature, reaches a minimum at − 80° and hen increases; the variation of the coefficient of xpansion, that is $\frac{1}{\alpha}\frac{d\alpha}{dt}$, diminishes when the temerature decreases and changes sign at − 80° from ositive to negative.



The accompanying diagram shows the course of he coefficient of expansion of carbon disulphide, he phenomenon proves certainly the existence of n anomaly in the change of density of the carbon isulphide with temperature. However, neither this henomenon nor an evident anomaly in the course f the dielectric constant of carbon disulphide[2] ecessitates the existence of two liquid phases of this ubstance, as my investigations on the specific heat ave proved that a transformation point does not xist in carbon disulphide.

Physical Characterization of Calf Thymus Nucleohistone

We have characterized calf thymus nucleohistone, prepared by modified Huiscamp[1] methods, by observation of its sedimentation velocity, sedimentation equilibrium, diffusion, viscosity and electrophoresis. Between pH 5·2 and pH 9·0 in buffers containing 5 per cent sodium chloride it is monodisperse, and close to pH 10·4 is irreversibly transformed into a homogeneous material having a smaller sedimentation constant than the original nucleohistone. In these buffers, the reciprocals of the sedimentation constants of the nucleohistone and its transformation product are linear functions of the protein concentration, and the limiting values of the sedimentation constants for zero protein concentration have been found.

Using the limiting value of the sedimentation constant, and the diffusion constant for dilute protein solutions containing 5 per cent sodium chloride, the molecular weight of the nucleohistone is found to be 2,200,000 in good agreement with the value 2,100,000 determined by sedimentation equilibrium. The sedimentation data indicate that the molecule is highly elongated.

In buffers of ionic strength 0·02–0·04 the molecule is less stable. This is true of solutions in neutral 2 per cent calcium chloride, in which the sedimentation constant is independent of protein concentration, and equal to the limiting value for 5 per cent sodium chloride – buffer solutions. Near pH 12 in 5 per cent sodium chloride – buffer solutions a precipitate is formed exhibiting the typical behaviour of a histone.

The electrophoretic behaviour was investigated in buffers of ionic strength varying from 0·02 to 0·08, using both types of Tiselius apparatus. The protein is insoluble in such buffers below pH 5, the insoluble region including the isoelectric point, which is estimated to be close to pH 4. From pH 5 to pH 9 the material is negatively charged and homogeneous electrophoretically. Dialysis against tenth normal sodium hydroxide followed by return to lower pH shows that the major part of the material is unaltered.

The effective charge of the protein molecule as calculated from titration data is not in agreement with the charge calculated from mobility data alone. This difference is attributed principally to the linear nature of the molecule, a length to width ratio of 50 being indicated.

The marked variation, with the ionic strength of buffer, found for the mobility is of the type required by the Debye-Hückel theory. Theoretical difficulties at present prevent the correlation of the absolute theoretical values with those found experimentally.

The rates of electrophoretic migration varied in the two sides of the U-tube, depending chiefly upon whether the initial migration had been from protein to buffer or vice-versa. It also varied with protein concentration. These variations appear to depend on several factors, including differences in conductivity and ionic strength, pH and viscosity on the two sides of the migrating boundary. Corrections determined for conductivity and ionic strength have been found to reduce the magnitude of the variations to about one half.

The molecular kinetic and electrophoretic behaviour of the protein appear to be independent of the method of preparation.

Oxidation of Succinate by Heart Muscle

It is widely held that the oxidation of succinate in animal tissues proceeds in the following manner:

Oxygen ⟷ Cytochrome Oxidase ⟷ Cytochromes ⟷
(*a*,*b*,*c*)
[Succinate ⇄ Fumarate
Succinic dehydrogenase].

It is assumed that no co-enzyme or intermediary hydrogen carrier is required to link succinic dehydrogenase to the cytochrome-cytochrome oxidase system[1]. This question has acquired special significance in view of the essential role of the succinic-fumaric acid system in cellular respiration which has been postulated by Szent-Györgyi[2].

Oxidase preparations obtained by the method of Keilin and Hartree[3] from beef heart muscle extracts by isoelectric precipitation catalyse the reduction of methylene blue by succinate under anaerobic conditions as well as the oxidation of succinate by molecular oxygen. Upon repeated isoelectric precipitation, the aerobic activity towards succinate is greatly impaired, whereas that towards hydroquinone is unaltered; in both cases an excess of cytochrome *c* was added.

When phosphate extracts from ground and washed heart muscle are spun in an ultracentrifuge at 384 r.p.s. for 30 minutes, a sediment is obtained which does not catalyse the aerobic oxidation of succinate in spite of the fact that such preparations, even after twice repeated sedimentation, contain cytochrome oxidase, cytochrome *a*, *b* and *c*, and succinic dehydrogenase[4]. The ability to oxidize succinate aerobically is restored by the addition of small amounts of the clear, supernatant fluid obtained by the ultracentrifugation of crude heart muscle extracts. It exerts its activating power also towards oxidase preparations which have been partially inactivated by repeated isoelectric precipitation. The supernatant fluid alone is inactive towards succinate even in the presence of an excess of cytochrome *c*.

The activating principle present in the supernatant fluid is not dialysable, but it is inactivated upon dialysis against large volumes of phosphate buffer, *p*H 7·4. It is partly destroyed when the crude extract is kept at 100° for 10 minutes, and it is precipitated by trichloroacetic acid. The rate at which the principle sediments in the quantity ultracentrifuge at 512 r.p.s. (field at the bottom of the tubes, 69,000 *g*) suggests a molecular weight of the order of 140,000.

The activating principle is not identical with catalase[5] or with aluminium[6]. It may represent the factor the removal of which in the experiments by Stotz and Hastings[7] and in those of Hopkins, Lutwak-Mann and Morgan[8] led to partial or complete inactivation of their oxidase preparations towards succinate. On the other hand, spectroscopic observations show that succinate when added to ultracentrifugally purified oxidase preparations causes the reduction of the cytochromes *a*, *b* and *c* present in such preparations as well as that of added cytochrome *c*. The concept that *the activating principle provides a coupling link between succinic dehydrogenase and the cytochrome-cytochrome oxidase system* would be valid only if it can be shown that the rate of reduction of cytochrome by the incomplete enzyme system is insufficient to bring about a measurable oxygen uptake under the conditions of the manometric experiments. This question, as well as the possible relationship of the activating principle to a flavoprotein[9], is under investigation.

The results of typical experiments will be found in the accompanying table:

Preparation	Time for reduction of methylene blue at *p*H 7·4 and 37°		Oxygen uptake (µl. in 60 min.) in presence of 5 mgm. dry weight of enzyme preparation at *p*H 7·4 and 37°; 0·033 mM. hydroquinone and succinate respectively			
	Succinate	Control	Hydroquinone	Hydroquinone + Cytochrome	Succinate + Cytochrome	Succinate + Cytochrome + Activator
1 × ultracentrifuged	—	—	—	—	0	392
3 × ultracentrifuged	3 min.	>60 min.	60	700	18	960
1 × isoelect. precipitated .. .	4 min.	>60 min.	—	720	545	—
3 × isoelect. precipitated .. .	7 min.	>60 min.	—	760	120	—
3 × isoelect. precipitated, after 48 hr. ..	—	—	—	—	0	176

This investigation was aided by a grant from th Jane Coffin Childs Memorial Fund for Medica Research.

Poly-condensation of α-Amino Acid Esters

Under different experimental conditions, ther can be obtained from glycine ethyl ester, among oth known products, polypeptide esters of various cha lengths.

(1) Solutions of glycine ethyl ester in vario solvents, kept either at room temperature or boilir point, deposit precipitates on long standing fro which a number of fractions were isolated. Th

analytical data of some representative fractions correspond to the following new compounds: dodeka-glycine ethyl ester (solvent: xylene at room temperature); trideka-glycine ethyl ester (solvent: xylene at boiling temperature); heptadeka-glycine ethyl ester (solvent: benzene at boiling temperature).

(2) On passing oxygen or hydrogen through free glycine ethyl ester, the liquid gradually solidifies. After standing several weeks, there were isolated hexadeka-glycine ethyl ester from the oxygen-treated ester and eikosi-glycine ethyl ester from the hydrogen-treated ester.

It appears that, under suitable conditions, glycine ethyl ester can be condensed into linear chains of considerable length. The products are hornlike and practically insoluble even in hot water.

As in the case of other high-condensation products, it should be borne in mind that, although the analytical data and the chemical properties found are in agreement with the formulæ given, they might correspond also to mixtures of hitherto unknown peptide ester homologues of high chain length.

(3) The ability to form linear chains is not confined to glycine ethyl ester; thus alanine ethyl ester of which the only direct condensation product hitherto known was alanine anhydride) yields under suitable conditions, *inter alia*, condensation products which give a strong biuret reaction and seem to be alanine polypeptide esters.

Systematic experiments on the behaviour of various esters of the different representative amino-acids and their peptides are in progress.

A Chromatographic Study of Lignite

WE find that the Tswett technique is appropriate for the accumulation and isolation of some interesting compounds occurring in lignites. Thus, light petroleum was allowed to percolate through 00 kgm. of lignite (coming from Várpalota, Hungary); the petroleum was sucked through a calcium hydroxide column. In this way the solvent is eliminated and the adsorbent shows different layers, especially under a quartz lamp.

After having eluted the upper half of the column by using alcohol – light petroleum mixtures, we kept the liquid at 0° and observed the formation of water-soluble needles or prisms (15 mgm.). This sample, a potassium salt, is a powerful reducing agent which apparently belongs to the ascorbic – reducing acid – reductone group. Dichlorphenol-indophenol, silver nitrate and selenic acid are instantly reduced at room temperature, but Fehling's solution is reduced only when heated. Iodine is decolourized rapidly in the cold. Ferric chloride produces a dark violet tint on the surface of the crystals.

If the filtrate of the salt mentioned above is washed free of alcohol and repeatedly chromatographed, a second, well crystallized but water-insoluble compound appears (150–300 mgm.) which seems to belong to the triterpene class. It gives the usual sterol reactions but is not precipitated by digitonine. Colourless prisms (from acetone), m.p. 244–247° (decomp., uncorr.); lævorotatory; molecular weight in camphor, close to 400.

The chromatographic investigation of raw extracts of lignite was facilitated by a broad pink zone in the column, which deepens and becomes dark wine red, by elutriation with alcohol. Furthermore, it slowly becomes light yellow when kept in an open flask; this change is rapid, however, if carbon dioxide is introduced. So far we have not succeeded in crystallizing the compound responsible for these phenomena, possibly because it is accompanied by abundant quantities of resin.

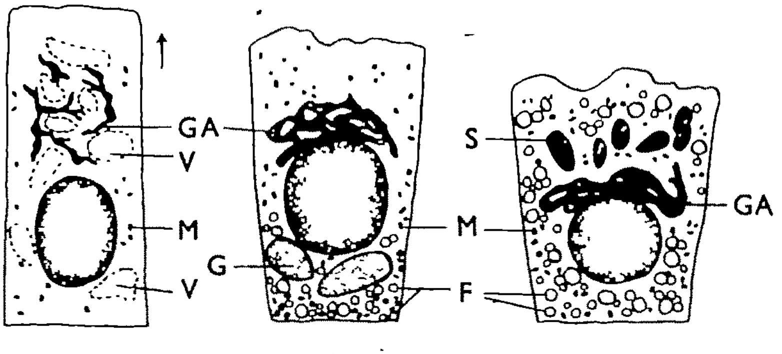
Cytology of the Human Uterine Gland Cell

ONLY one type of cell is to be found in the uterine glands. Some of these cells may be ciliated, but are otherwise like the non-ciliated cells. In the proliferative and premenstrual phases (*b*), the normal constituents of these cells are mitochondria (*M*), Golgi apparatus (*GA*), fat (*F*) and glycogen (*G*). No formed secretions otherwise are found. Throughout the entire intermenstrual period, the Golgi apparatus remains juxta-nuclear and confined, but at menstruation (*a*), in the deeper parts of the glands, which are not broken down, a diffuse apparently secretory phase begins (*V*), closely resembling the secretion phases of such glands as those of the epididymis or pancreas islet cells. The surviving postmenstrual uterine gland cells have a clear cytoplasm and small juxta-nuclear Golgi apparatus. Thus, except just at menstruation, no satisfactory evidence for secretion by uterine glands during the normal intermenstrual phases could be found. There is, as has been mentioned, extensive storage of fat (premenstrual) and glycogen, and the lumen of the gland often shows a material which stains well in muchæmatein and mucicarmine, whatever value can be attached to these methods.



a MENSTRUAL *b* PREMENSTRUAL *c* PREGNANCY

But it is at pregnancy (*c*) that a true secretion (*S*) appears in the outer parts of the cells, in front of each Golgi apparatus. This is found in considerable quantities, and is in the form of droplets stainable in iron alum hæmatoxylin, and faintly in osmium tetroxide solution.

Thus we have concluded that two possible phases of secretion may occur in the human uterine gland cells—one just before or during menstruation—as might be concluded by the loosening out and breaking up of the Golgi apparatus, the other quite certainly a 'solid', probably protein secretion, which only appears at pregnancy.

This work was made possible by the Irish Medical Research Council. A fuller account will be published later.

Spontaneous Yellow Fever in Rhesus Monkeys in the Absence of Mosquitoes

Before a satisfactory method of prophylactic immunization had been devised, yellow fever was by no means uncommon among laboratory workers, some 37 cases having been reported. In every instance, those who contracted the disease had been in close contact with material containing either the virulent pantropic or the neurotropic strains of yellow fever virus, and the portal of entry was the skin, conjunctiva or nasopharyngeal mucosa.

During the past winter, two rhesus monkeys, *Macaca mulatta*, kept under laboratory conditions, at an interval of 71 days, have developed and died from spontaneous yellow fever. The monkeys were in two separate animal houses. In the case of the first animal, no other monkey infected with yellow fever had been in the same room for just over three months, while the second animal was in a room where no other infected monkeys had been for nearly six months. No virulent pantropic virus was in use in the laboratory during the period.

The method of infection is at present unknown, but human agency can be ruled out, since the stock of virulent yellow fever virus is under strict control and can be fully accounted for. Mosquitoes were entirely absent from the animal houses, but certain ectoparasites, monkey lice and rat fleas, *Ceratophyllus fasciatus*, were found. In addition, cockroaches, *Blatella germanica*, and a small ant, *Monomorium pharaonis*, were present. Experiments are at present being carried out to determine whether these arthropods were in any way responsible for the spontaneous infection of the monkeys.

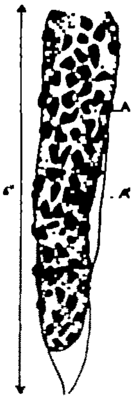
Reproductive Cycle in *Salmo salar* Linn.

It is known that in *Salmo salar* Linn. there occurs regularly a very small percentage, possibly of the order of 0·1 per cent, of mature female fish in which discharge of ova may be delayed or does not take place. Such fish are found many months after the normal spawning time heavy with ripe ova. In certain parts of Scotland they are termed 'baggots' or 'baggits' by fishermen.

Beyond the tacit assumption by some that a high rate of mortality supervenes, data of the subsequent behaviour and condition of such fish are scanty.

It is desirable, therefore, to record an instance where a marked degree of recovery appears to have taken place. Part of an ovary and some scales fro an outwardly normal 16 lb. spring fish caught b rod in the River Dee near Llangollen in March wer sent by Mr. G. M. King to Mr. W. J. Menzies, chie inspector of salmon fisheries, Edinburgh, from who I received the former specimen, accompanied by the following data:



"The scales show the fish to hav been a two years' smolt, and then t have ascended into fresh water as a small spring fish, after approximatel two years in the sea, in 1937.

"There is a perfectly good spawning mark for the winter of 1937–3 since when the fish has made approximately a year's normal growth in th sea."

External examination showed th ovary to have an apparently ful normal complement of aged ova opaque and straw-coloured, betwee which were visible abundan young healthy ova—coral pink in colour—o the type normally present in female fish ascendin in the spring. A section of the ovary (see accompanying diagram) showed a compact mass of old (A) an new (A^1) ova, the former in various stages of resorption, most of them shrunken and further distorte in shape by the pressure of the infiltrating new crop.

The general condition of the specimen was consistent with the probability that had the fish remained in the river the young ova would hav developed to full maturity by the autumn spawnin period. Whether they in turn would have been undischarged remains uncertain pending knowledge o the controlling mechanism in teleostean fishes.

Large-scale Plankton Culture

The new Oceanographic Institute which Göteborg' Vetenskaps- och Vitterhetssamhälle owes to th munificence of the late Mr. K. A. Wallenberg i provided with a vertical plankton shaft, two metre in diameter and twelve metres deep, which afford facilities for culture experiments on a fairly larg scale. Sea water is passed through a sand filter an sterilized by a powerful quartz lamp before enterin the shaft from below. It is cooled by means of refrigerating plant which sends cold brine to tw systems of cooling coils, one near the top, the othe halfway down the shaft. The illumination plant consists of two mercury lamps of 50,000 lumen each an four sodium lamps of 10,000 lumen, mounted unde a large reflector.

In our experiments, the shaft was filled with stratified sea water: an upper column of 28 per mill salinity, 5·5 m. high, to which nitrate, phosphate silicate and soil extract had been added, and a lowe column of 35 per mille salinity which served to rais the column of culture medium to near the top o the shaft. The temperature was kept at about 9° C in the experiments with phytoplankton and at 6° wit zooplankton. With half the set of lamps burning surface illumination of about 30,000 lux was maintained for 8–10 hours per diem. At 1 m. depth th intensity was reduced to one half or less.

Raw plankton from the fjords or the open Kattegat ollected during the spring increase was repeatedly ntroduced into the culture column and the growth f the population followed by plankton counts. The istribution of suspended particles was also observed y means of a small transparency meter[1]. Water mples from the shaft were inoculated with pure ltures of diatoms, and their growth, which was uite rapid, was recorded photometrically. This roved that the water in the shaft retained its non-xic properties for at least several weeks.

Of the diatoms, *Skeletonema costatum* showed bundant growth; the number of cells introduced creased from 43 millions to about 3,120 millions, at is, seventy-three times, in the course of twenty-ne days. In another experiment the number of *hizosolenia alata* f. *gracillima* increased fivefold in ght days while other diatoms remained in good ndition during the same time although without crease in number. Several autotroph flagellates, -6 μ in length, showed an enormous increase during e first experiment. Convection currents deposited any diatoms on the cooling coils and these, together ith the flagellates, formed a green coating around the pes. It is hoped in future to eliminate this comication.

In later experiments the plankton samples introced consisted mainly of copepods which thrived ell in the shaft, a considerable number remaining ive as long as three weeks. They showed a remarkly uniform phototactic response involving rapid igrations towards or away from sources of light of fferent intensity.

Experiments are now being undertaken with pure ltures of diatoms in order to investigate the intertion between the plant cells and the surrounding edium under carefully controlled conditions. Later, tempts will be made to grow fish larvæ in the aft and to study their growth and their distribution der varying light, temperature and salinity nditions.

Demes: a Suggested New Terminology

IN the course of work on the experimental deitation of botanical groups, the need has arisen a term which can be applied to any specified semblage of taxonomically closely related indiduals. Such phrases as 'local intrabreeding populans' or 'populations occupying a specific ecological bitat' are cumbersome, and it is felt that a more ncise terminology would be useful and, further, uld focus attention on certain concepts undoubtedly great importance in the study of intra-group riation. We propose the term *deme** (from the eek δῆμος) for this purpose, with appropriate prees to denote particular kinds of demes. For mple, in a taxonomic group consisting of a number potentially interfertile individuals all the indiduals do not have an equal chance of interbreeding nature. The tendency is for individuals in close ximity to interbreed more frequently with each er than with individuals at a distance, and thus all, more or less isolated intrabreeding colonies set up. The distinctive features so commonly exhibited by local communities, for example, of sea plantain, provide evidence of this. These 'breeding communities' are likely to become increasingly important in the intensive study of evolutionary problems and we propose to name them *gamodemes*. It is clear that there are various degrees of isolation between such gamodemes, and when more experimental work has been done on this point it should be possible to devise a method of expressing degree of isolation quantitatively. At present, however, the concepts must remain somewhat vague, as is indicated in the definition given below.

Similarly we propose the terms *topodeme* and *ecodeme* to denote demes occupying specified geographical areas and specified ecological habitats respectively. These demes, however, must not be confused with the categories of experimental taxonomy. For example, the term ecodeme is not a substitute for the experimental taxonomic term ecotype. Ecotypes can be established only after an examination of numerous habitat populations, whereas the term ecodeme has reference to any habitat population irrespective of whether its ecotypic significance is or is not known. Whether the deme concept may entail a system of nomenclature for naming individual demes is a matter for future experience; but we would emphasize that any such system should be kept quite separate, both in form and in function, from systems of taxonomic nomenclature.

It should also be emphasized that these concepts do not necessarily imply the possession of any morphological characters in common between the individuals comprising a gamo-, topo- or ecodeme, other than those characters possessed in virtue of membership of the taxonomic group under consideration. For example, the populations of *Helianthemum polifolium* in Somerset and Devon would belong to separate gamodemes in virtue of the impossibility of their interbreeding in nature, even if no morphological differences could be discovered between them. The same considerations apply to topodemes and ecodemes. For example, two populations of a species from sand-dunes in Devon and in Scotland would belong to the same 'sand-dune ecodeme', even if the morphological differences between them were considerable.

At the same time, there will frequently, of course, be some degree of correlation between demes and intra-specific categories based on morphological criteria. It is hoped that one of the advantages resulting from this new terminology will be to bring out the degree of correlation in particular cases.

The definitions of the new terms are as follows:

Deme: any assemblage of taxonomically closely related individuals.

Gamodeme: a deme forming a more or less isolated local intrabreeding community.

Topodeme: a deme occupying any specified geographical area.

Ecodeme: a deme occupying any specified ecological habitat.

* This word has already been used by Geddes ("Encycl. Brit.", 16, p. 843; 1883) and by Perrier ("Les colonies animales et la formation des organismes", p. 721; 1898), to denote an aggregate of single cells, but so far as we can discover this use is now quite obsolete, and it appears permissible to revive it in another sense.

Effect of the Fungicide 'Granosan' on Atypical Growth and Chromosome Doubling in Plants

IN studying the effect of several insecticides and fungicides upon the procedure of meiotic processes I found that they induce a series of abnormalities, which further lead to production of hereditary variations, thus speeding up the process of the 'degeneration of the pure lines' in various degrees[1,2].

I studied recently the effect of the fungicide 'Granosan' (2 parts of CH_3CH_2HgCl + 98 parts of talc) upon mitosis. Treating germinating grains of *Secale cereale*, *Triticum vulgare*, *T. persicum*, *T. durum*, *T. polonicum*, and *T. ægilopoides* with 0·5–0·1 per cent Granosan (that is, 0·01–0·002 per cent ethyl mercury chloride) for 3–6 days (some experiments were continued for three weeks) swellings of the root tips and of the whole seedlings occurred. Studying these seedlings cytologically, I found that the agent has induced abnormal mitosis similar to those induced by colchicine and acenaphthene, namely, failure of (rather abnormal) achromatic figures, chromosome multiplications, multinucleations, and formation of large amœboid nuclei.

Occasionally chromosome doubling and larg nuclei in the root tips of similarly treated seedling of *Pisum sativum* occurred; but amœboid nuclei an multinucleations were not so frequently observec Consequently, Granosan is a more effective agent treating leguminous plants than acenaphthen Germinating seeds treated by Granosan for inductio of polyploidy are not attacked by fungi, whi those treated by colchicine are usually severel attacked.

The induction of atypical growth and chromosom doubling in Gramineæ by Granosan, and in a degre of colchicine and acenaphthene, shows that thes biologically active properties of the compounds hav nothing to do with the cyclic or heterocyclic structur of the molecules of the active compounds.

Points from Foregoing Letters

H. Carmichael and C.-N. Chou have measured cosmic ray ionization bursts underground and have calculated the rate of production of such bursts by mesons; they obtain fair agreement. Their measurements of bursts at sea-level, however, provide evidence of wide cosmic ray showers which originate in the atmosphere but evidently do not come from mesons. These wide air showers may be of two kinds.

In order to explain the anomalous dense spacing of nuclear resonance levels in the region of the rare earths, I. Gurevich suggests that nuclear matter undergoes a phase-transition at a certain temperature in a similar way as liquid helium and conductivity electrons in metals.

E. J. W. Verwey finds that the transition point in magnetite at about 120° K. is of electronic nature, and is probably connected with an order-disorder transition in the distribution of 8 electrons about 16 equivalent metal ions in the unit crystal cell. When a sample of pure, sintered magnetite is cooled a sudden increase of the electrical resistance by a factor of the order 100 occurs at the transition temperature; this phenomenon can be suppressed, however, by an excess of oxygen in the lattice.

In his investigations of the change in the coefficient of expansion α of CS_2 at low temperatures (+ 20° to − 112°), J. Mazur finds that the minimum of α is reached at a temperature of −80° C.

R. O. Carter and J. L. Hall find the molecular weight of calf thymus nucleohistone to be approximately 2,100,000 and the molecule to be highly elongated. The protein is electrophoretically homogeneous but the effective charge of the molecule calculated from titration data is not in agreement with the charge calculated from mobility data alone.

Contrary to our present views, Kurt G. Stern and Joseph L. Melnick have found that a heart muscle preparation containing succinic dehydrogenase, cytochromes *a*, *b* and *c*, and cytochrome oxidase is unable to catalyse the oxidation of succinate by molecular oxygen. When an activating principle of prote nature is added to the system, the aerobic activit towards succinate is restored.

M. Frankel and E. Katchalski state that certai amino acid esters (glycine ethyl ester, alanine eth ester) can under suitable conditions be condense to hitherto unknown polypeptide esters of conside able chain length.

L. Zechmeister and O. Frehden find that tl accumulation and isolation of two interesting com pounds can be carried out by submitting a petroleu extract of lignite to the chromatographic analysi one, showing high reducing power and belonging the ascorbic acid-reducing acid-reductone group, a another, which seems to belong to the triterpene

J. B. Gatenby and Olive E. Aykroyd have show that curettings from early interrupted pregnan cases may be recognized by the presence of lar secretion granules in the uterine gland cells.

G. M. Findlay and F. O. MacCallum state th spontaneous yellow fever has occurred, at an interv of 71 days, in two rhesus monkeys, *Macaca mulat* kept under laboratory conditions in separate anim houses. Mosquitoes were not present, but certa arthropods, which must be considered as possib vectors, were found.

An instance is recorded by R. M. Neill of a fema salmon (*S. salar*) returning to sea, after spawni migration with matured ova undischarged and aft a year's normal growth in the sea, reascending in fresh water; when the ovary showed in addition undischarged ova in an advanced stage of resorptc a new crop of young developing ova normal to fl ascending in spring.

H. Pettersson, F. Gross and F. Koczy describe vertical plankton shaft which affords facilities culture experiments on a large scale. Satisfacto results were obtained with both phyto- and z plankton.

RESEARCH ITEMS

Skin of Rebirth

Dr. Maurice Canney has collected a number of examples of the magical significance of animal skins among modern primitive peoples and compares it with belief current in ancient Egypt (*Man*, July 1939). Among the Bantus, children before reaching the age of circumcision had to go through a ceremony, the name of which means "to be born again". The child was invested in part of the skin and skin of the big stomach of a male sheep which had been killed by the father. It then had to go and lie on a bed by its mother and cry like a new-born infant. In funeral ceremonies of the elders, burial was not complete without a skin of a sheep or a bullock if the family could afford it. The corpse was laid out in the prenatal position and the skin, hair upward, laid upon it. Among the Ila-speaking peoples a corpse was first put in three dry skins. A great slaughter of beasts took place at a funeral. Five large oxen were called the wrapping-up cattle, because their skins were laid in the bottom of the grave, and wrapped around the corpse arranged in the prenatal position. Among the Lango it is noted that the corpse was carried to the grave in the sleeping hide of the deceased, and it was buried with him. Over the grave a sheep was killed for the funeral meal. The skin of this was worn afterwards on the head of the nearest relative. This evidence suggests the survival of an idea prevalent in ancient Egypt. In the legend of the Wandering of Isis in the Delta the goddess said to Horus *inter alia* that he was "the son of him that is in Mesqet" this being the name of the bull's skin, in which the deceased was placed to secure for him the new life. In the Egyptian religion the most important of the rites of initiation was one called the mystery of animal rebirth; and in it as depicted in the Theban tombs a priest is shown in a sleigh crouching under a skin in the position of a foetus. When he comes forth from the skin, he is supposed to be reborn. Skins have the same significance in belief in India.

The Last of the Dinosaurs

The Smithsonian Institution reports that in Upper Cretaceous rocks in central Utah explorations by palæontologists from the Institution have revealed considerable fossil skeletal remains of titanosaurs. The discovery is interesting because, although the presence of these gigantic plant-eating dinosaurs had been known from a wide area, including India, Indo-China, Madagascar, France and South America, only two bones found in New Mexico in 1921 had indicated their habitation of North America, until the Utah finds of the past two summers. Moreover, they and the horned dinosaurs and 'duck-bills' also represented in the same beds were amongst the latest to survive of the giant reptiles, and although no break has been found in geological conditions between these Upper Cretaceous beds and the succeeding Palæocene sufficient to suggest a cause for their sudden disappearance, there is a possibility that the formation constitutes a bridge between the closing of the great reptilian age and the dawn of the mammalian epoch. It may therefore yet yield a clue to two of the most momentous steps in the evolution of animal life.

Cytology and Taxonomy of Calochortus

The genus Calochortus is a difficult one for systematists. By combined cytological and morphological study, J. M. Beal (*Bot. Gaz.*, 100, 528–547; 1939) has defined the limits of some sections of the genus. Of 28 species, those with $n = 10$ and capsules winged on the angles are placed in Eucalochortus, while the remainder with a basic chromosome number other than 10 are placed in Mariposa, except one, *C. plummeræ*, $n = 9$, which is placed in Cyclobothra. Seven is considered to be the basic number of Mariposa and possibly of the genus. Evidence is given suggesting ways in which other chromosome numbers have been derived from seven.

Food Value of Broccoli

E. Vanstone and C. E. H. Knapman (*J. Pom.*, 17, 85; 1939) have determined the amounts of nitrogen, phosphorus, potash and lime removed from the soil by Roscoff broccoli grown in different localities on commercial farms and on experimental plots at Seale Hayne. They found that the composition of the plant was approximately constant regardless of location and manuring. The average amounts of minerals removed from the soil per acre were: potash 240 lb., nitrogen 204 lb., lime 110 lb., and phosphoric acid 70 lb. Good quality curds differed from those of inferior quality ('soft curds') by having a higher percentage of potash and lower nitrogen. Plants sown in April and transplanted in June, grew most rapidly during September, October and November and matured the following April. Minerals were absorbed continuously throughout the growing period. The composition of the dry matter of the curd was compared with that of dried milk and found to be higher in protein (40 per cent), higher in ash (12 per cent) and equal in carbohydrate (36 per cent). The curd is evidently a highly nutritious food, rich in protein and mineral matter but deficient in fat. The leaves of the broccoli plant account for half the total dry weight, and though these are not used for human consumption they represent a valuable food for cattle, especially for dairy stock. They compare favourably in protein, oil and carbohydrate content with palm kernel cake and young grass, and are superior to these in that they contain less fibre and more mineral matter.

Nodule Organisms of the Leguminosæ

The discovery, towards the end of last century, of the peculiar symbiotic nitrogen metabolism of leguminous plants was quickly followed by the knowledge that each plant species required a particular strain of the appropriate organism, *Pseudomonas radicicola*. This led in practice to the tabulation of plant-bacteria groups, but certain difficulties arose, and necessitated a re-survey of the whole question. J. K. Wilson undertook this task upon an adequate scale, and his results have recently been published (*Cornell Univ. Agr. Exp. Sta. Mem.* 221, Ithaca, U.S.A., March 1939). More than 12,000 tests were made with about 200 plant species from 70 genera, and 32 strains of the organism, all made under sterile conditions. This imposing volume of experimental result leads to the conclusion that plant-bacteria groups are likely to be somewhat tentative. They should still be useful in practice, but several plants which had not previously been assigned to a group could be placed in the present investigation, in as many as twelve of them. Other plants, moreover, will symbiose with almost any of the strains. *Phaseolus coccineus* and other species have symbiosed simultaneously with four or five strains of the organism. Morphological studies have also been prosecuted, and it is further suggested that organisms with restricted range of symbiosis are predominantly monotrichic, whereas those with extended symbiosis include also forms with several flagella.

Structure of Proteins

THE picture of the structure of proteins proposed by Emil Fischer regards them as polypeptide chains, and this has been extended by the assumption of hydrogen bonds and other weak interatomic forces acting between chains and their parts. The so-called cyclol hypothesis postulates hexagonal rings resulting from the transfer of hydrogen atoms from secondary amino to carbonyl groups with the formation of single C—N bonds. In a comprehensive paper, L. Pauling and C. Niemann (*J. Amer. Chem. Soc.*, 61, 1860; 1939) review several lines of experimental evidence bearing on this question. X-ray work is not regarded as providing satisfactory evidence for the cyclol theory, and several investigations have provided strong (but not rigorous) evidence for polypeptide chains in fibrous proteins. The great complexity of proteins, however, makes it unlikely that a complete structure determination by X-ray methods is possible. Heats of combustion and bond energies show that the cyclol structure cannot be of primary importance for proteins; a cyclol structure would be considerably less stable than a polypeptide one. Interatomic distances in the cyclol structure have improbable values, and the presence of large numbers of hydroxyl groups postulated in it seems to be negatived by experiments on the acylation and alkylation of proteins. No simple substances with the cyclol structure have been synthesized so far. Among the arguments used in favour of the cyclol hypothesis, that of the total number of amino acid residues per molecule, and a further modification involving imino acids, are said to lack force. Recent evidence shows that proteins in films have the polypeptide structure. The authors give a concise summary of their own views on the protein problem. They believe that the chains or rings contain many amino acid residues, usually several hundred. A native protein molecule possesses a definite configuration involving the coiling of the polypeptide chain or chains in a definite way, brought about mainly by hydrogen bonds. A wide range of configurations is regarded as probable. The number of each individual amino acid residue and the total number of all amino acid residues in the molecule can be expressed as powers of the integers two and three, and there is perhaps some significance in the number 288 of residues in the simple proteins.

Reactions of Methyl Radicals

AN extension of previous work on the reactions of methyl radicals has just been published by H. S. Taylor and J. O. Smith (*J. Chem. Phys.*, 7, 390; 1939). Methyl radicals, produced by the photolysis of mercury dimethyl, were allowed to react with deuterium, ethane, normal and *iso*-butane, and neopentane, and the amounts of methane and ethane formed were determined. The plot of the logarithm of the rate of formation of methane against 1/temperature (abs.) is a straight line for all the reactions. To obtain a satisfactory mechanism for the reaction between mercury dimethyl and hydrogen or deuterium proved troublesome because of the number and variety of facts which the mechanism was required to satisfy, but it has been successfully accomplished. The most important of these facts are that both in the absence and in the presence of hydrogen or deuterium the formation of ethane remains unchanged; formation of methane increases with temperature and so does the rate of decomposition of the mercury dimethyl; formation of ethane shows first-order dependence on light intensity, whilst formation of methane shows an order between one-half and the first power, tending to the first power with increased temperature; packing the vessel, at 200°, cuts down the amount of methane formed but does not affect the amount of ethane; and the rate of decomposition of mercury dimethyl is independent of its concentration. For the interactions with the hydrocarbons the suggested mechanism is (i) $CH_3 + RH = CH_4 + R$; (ii) $R + CH_3 = RCH_3$; (iii) $CH_3 + CH_3 = C_2H_6$. From the rate of formation of methane the following activation energies for the reactions of methyl radicals with hydrocarbons, assuming zero activation for ethane formation, have been deduced: ethane and neopentane, 8·3; *n*-butane, 5·5; *iso*-butane, 4·2 kg.-cal. The differences in activation energies are attributed to differences in bond energies, particularly because of the closely analogous differences observed by Kistiakowsky in the heats of hydrogenation of substituted ethylenes.

Motion Pictures of Small Chromospheric Flocculi

SOME interesting facts on chromospheric phenomena are given by Robert R. McMath in a recent paper with the above title (*Mon. Not. Roy. Astro. Soc.*, 99, 7; May 1939). In August 1938, Mr. H. E. Sawyer was taking motion pictures of a dark hydrogen flocculus at the McMath-Hulbert Observatory, and displaced the second slit one half angstrom towards the violet with the object of registering a portion of the flocculus which showed velocity in the line of sight when examined in the spectrohelioscope. Sufficient exposures were made to provide a run on the screen when the spectroheliograms were shown by means of a motion picture projector. The motions of the small, dark flocculi were clearly seen, and it was obvious that a motion picture of the fine chromospheric detail had been secured. When the experiment was repeated with the second slit displaced one half angstrom towards the red, the pictures showed the same phenomena, but not so definitely. The author describes the surface of the sun seen in these pictures as like "an ocean viewed directly from above, and covered completely with short and choppy billows in a constant progression of irregular growth and recession". Accurate determination of the mean life-period of the flocculi involves careful identification of the markings measured on successive motion picture frames. For this purpose a high speed in taking individual frames is necessary, perhaps as high as eight per second, and it is hoped that sufficient material will be at hand this summer to undertake such research.

THE LEONARDO DA VINCI EXHIBITION AT MILAN

THE Exhibition of Leonardo da Vinci (1452–1519) which has been staged in the Palazzo dell' Arte n Milan is a truly comprehensive and magnificent estimony to the many-sided activities of the great master. Endeavour has been made not only to ollect exhaustive examples of his multifarious nterests, but also to illustrate his personal environment and record, and thus ensure a finer appreciation f the man himself. There are galleries devoted to ocuments connected with his life-history, to his brary, and to portraiture of him both in painting nd sculpture. To provide background, other rooms now the work of his masters, his contemporaries at lorence and at Milan, and the pupils of his school.

In the Hall of Honour there are numerous drawings nd designs of da Vinci, and in other galleries examples of his sculpture and some copies of his paintngs. This splendid symposium, generously subscribed rom public and private collections in many countries, manifest his superb mastery in drawing and design.

None the less staggering are his manifold achievements in the field of science. Anatomy and botany ach occupy a gallery; these two subjects of natural cience are known to have stirred Leonardo deeply, nd the far-seeing results of his investigations are ell portrayed.

In the realm of physics and mathematics he was head of his age. In several rooms there can be een models and charts and diagrams of his work n astronomy, optics, mathematics, or again on eology and geophysics. His service under various masters necessitated his turning his mind to architecture and town-planning: a series of fine models nd drawings bear testimony to his power of blending balanced and artistic outline with the practical eeds of utility.

It is perhaps natural that much space in the xhibition has been devoted to a record of his ngineering qualities. Two hundred models, some full size and some on a reduced scale, have been faithfully reconstructed from da Vinci's own elaborate notes, drawings and dimensions in the "Codice Atlantico" and other documents, and bear ample witness to his amazing versatility.

The flight of birds aroused his keenest interest and study, and he was convinced that man could achieve flight with mechanical aid: the models and records of his designs in this direction are indications of his insight into the future. Similarly his realization of natural forces prompted his investigations of the action of the waves and the winds: his designs for ships, with single or double hulls, and for paddle steamers, were the outcome of this research and betray a mind more fertile and far-seeing than any of his contemporaries.

Innumerable models and drawings give evidence of da Vinci's ingenuity and power of invention in mechanical devices of almost every kind. Pumps and all manner of hydraulics are notable examples, and one is tempted to run the gamut of all his varied achievements in mechanical engineering: it must suffice, however, to mention only a few examples, such as a printing-press, differential gear, cranes, water wheels, fire-escape ladder, belt-driven machines, in order to disclose his grasp of mechanical forces and the multifarious uses to which they could be put.

The wars of the period inevitably drew a man of his ability into their net, and his genious as a military engineer made his services invaluable to his chiefs. His study of ballistics stood him in great stead, and models of his multiple gun, bridges and fortifications are records of the adaptability of his great knowledge. It only remains to say that space has not been stinted at the Exhibition: the lay-out is good and modern. Skilful use has been made of murals and drawings and appropriate wall or ceiling decoration: the result is not only attractive but intensely interesting. The Exhibition remains open until October 1.

UNIVERSITY STATISTICS IN GREAT BRITAIN, 1937-38*

THE returns recently published by the University Grants Committee show that the total number f full-time university students in Great Britain coninues to diminish. A gradual decline has been ontinuous since 1934 and would have been more noticeable after 1935 but for a simultaneous increase n the number of students from overseas. The actual igures are as follows:

	From overseas	Other full-time students
1933–34	4,670	46,067
1934–35	4,653	45,985
1935–36	4,718	45,811
1936–37	4,989	44,700
1937–38	5,096	44,093

The decline has been most marked in Wales, where the number fell by 15 per cent between 1935 and 1938, after a rise of 18 per cent in the preceding four years. The falling off in the Scottish universities, to which attention was directed in the Grants Committee's last quinquennial report (for 1929–35), has continued but was very slight last year when, moreover, admissions showed a sharp rise of 248. Admissions in Great Britain as a whole showed a rise of 295 following decreases of 423, 296, 374 and 189 in the four preceding years.

Distribution of the whole body of full-time students over the different subject groups during recent years is shown in the accompanying diagram. It exhibits a remarkable upward trend under the head of medicine (including dentistry). During the years in question the proportion of women students of medicine and dentistry increased from 12 to 14. Research and other advanced studies continue to occupy an increasing number of full-time students. The years 1929–35 showed an increase of no less than 35 per cent in their number, although in the preceding quinquennium there had been practically no increase. Since 1935 there has been a further rise of 5 per cent and they now constitute more than 6 per cent of the total of all full-time students.

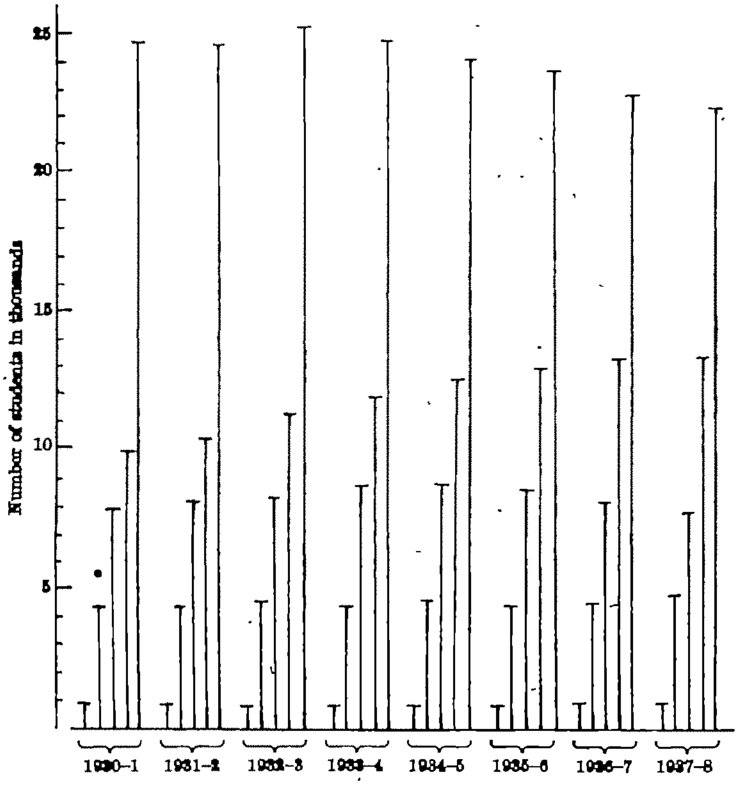
---

* Returns from Universities and University Colleges in receipt of reasury Grant, Academic Year 1937–38. Pp. 28. (London: H.M. tationery Office, 1939.) 1s. net.

Conditions of residence of full-time students are indicated by the following figures: residing in colleges and hostels, men 8,124, women 4,314; in lodgings, men 14,190, women 2,163; at home, men 15,576, women 4,822. The subject was discussed at considerable length in the quinquennial report 1929–35 and the Commissioners extolled the value of properly equipped and managed halls of residence. Recently their opinions have been echoed in the National Union of Teachers' report on the training of teachers, which points out that for prospective teachers who live at home while taking the four years approved course, university life becomes little more than a prolongation of school-days, while lacking such elements of community life as school provided, and where the journey between home and university is a matter of hours, as is often the case, these precious years tend to be squandered in an incessant rush of trains, lectures and preparation of work. The report goes so far as to recommend that *all* students attending this course should live either in a residential college or a college hostel, and that residence fees should be brought within the means of the poorest student. The following table shows that Sheffield and St. Andrews are the only universities in which there has been any marked advance in this respec since 1935:

Students in colleges and hostels.

	Increase or decrease since 1935	Percentage ratio to all full-time students 1935	1938
England (excluding Oxford and Cambridge)	+112	18·9	19·8
Wales	−26	15·3	17·2
Scotland	+61	8·2	9·1
Total	+147	15·8	16·9
Reading	+21	68·3	76·4
Bristol	−17	37·2	35·9
Durham	−18	31·0	32·2
Leeds	−12	23·4	21·1
Manchester	−56	20·7	20 9
Sheffield	+82	9 5	20 2
Birmingham	+1	12 5	13·7
London	+54	12·0	12·4
Liverpool	−3	10·1	10·4
St. Andrews	+64	24·0	31·2
Edinburgh	−31	13·9	13·7
Glasgow	+21	3·5	4·3
Aberdeen	—	—	—



Groups of five vertical lines represent number of students in one academic year in agriculture, technology, pure science, medicine and arts respectively, reading from left to right.

NUMBER OF STUDENTS ARRANGED BY SUBJECTS.

The most interesting feature c the returns is their inclusion fo the first time of information as t the educational origins of newl admitted students. This significan innovation takes the form of tabular statement of full-time graduating and diploma students entering for the first time in 1937–3 (i) whose homes were in the Unite Kingdom, and (ii) how many o these began their education in public elementary school. From Oxford and Cambridge and the Institute of Education, London, thi information was not forthcoming bu will be given in future returns. Th following table summarizes the figure for all the other institutions:

	(i)	(ii)	Percentag ratio (ii) to (
University of London	2,905	822	28·3
England	6,071	2,761	45·5
Wales	674	600	89·0
Scotland	2,221	1,371	61·7
Great Britain (Total)	8,966	4,732	52·8

Women included in the figures unde (ii) were: 252, 697, 166, 406 an 1,269 respectively.

Although the figures are far in deed from indicating approximatio to equality of educational oppor tunity, they show that there ha been much progress since the Cros Enquiry Commission of fifty year ago was told by a witness unde examination as to the prospects c a public elementary school pupil eve reaching a university: that it would be next t expecting him to take wings.

By way of supplement to this information, th Grants Committee publishes a table showing th proportion of 'assisted' to other full-time student this expression implying assistance from outsid sources (that is, other than personal and private namely, scholarships, exhibitions and other award and allowances providing wholly or in part for th payment of fees. The percentages are: Oxford an Cambridge, 44·7; London, 26·4; England, 38·5 Wales, 58·8; Scotland, 45·7; total, 41·9. The pe centage of assisted women students was 46; of men 4

PROGRESS IN BUILDING RESEARCH

ROGRESS towards the solution of many building problems is recorded in the annual report for 38 of the Building Research Board recently issued y the Department of Scientific and Industrial esearch (London : H.M. Stationery Office. 3*s.* 6*d.* net). ne of those pressing most urgently for investigation that of sound transmission in buildings, and in this here of activity the report claims that the position these inquiries has been very much advanced uring the past year. It has been made clear that buildings with a normal continuous rigid con- ruction it is virtually impossible to obtain a higher egree of sound insulation between two neighbouring oms greater than that obtainable with 9-inch brick alls on a concrete floor resting on sound insulators. eviewing, therefore, the results of experiments in e small steel frame building at the Research tation, in which various types of construction can tested, it is claimed that practical suggestions for nstruction to cut down sound transmission can w be advanced.

Special interest is attached to the work done in e preparation of artificial pozzolanas. The value the European natural pozzolanas has long been nown, the name being derived from the volcanic ust from the region of Pozzuole which the Romans ed in their mortars. These natural earths or olcanic tuffs have the ability to combine with lime d thereby to produce a hydraulic set which gave the ancients a cementing material suitable for a-walls, aqueducts and the like. A more important evelopment is their use with Portland cement hich, when used in soils containing sulphate salts, ffers serious deterioration from chemical attack. he work of the Research Station has provided the ethod whereby artificial pozzolanas have been roduced from certain clays and from refuse from e Scottish shale oil industry. Used with cement ortar these materials greatly increase its resistance sulphate attack, but somewhat diminish its early rength. Both natural and artificial pozzolanas ave been included in tests on the corrosion of steel inforcement in concrete piles exposed to sea-water, which are being carried out in conjunction with the Sea Action Committee of the Institution of Civil Engineers. The report notes that the manufacture of these materials is now beginning to be undertaken by the cement makers.

The spray method of cleaning buildings has been applied with success and its efficacy in particular circumstances has been the subject of experimental investigations. Most noteworthy among the latter is the cleaning of the Admiralty Screen in Whitehall, a Portland stone structure about 150 years old and the work of John Adams. Being almost completely soot-blackened it offered a severe test of the efficacy of the treatment.

A new branch of the work deals with ventilation problems, which are especially worthy of study in the interests of health and comfort. It is a subject which has received little attention and not much is known as to the distribution of air in buildings provided with the different mechanical ventilation or air-conditioning methods of to-day. The relative degree of purity of air supplied by upward or by downward ventilation is of considerable importance. The work in hand is primarily directed to the development of methods of testing the efficiency of different types of air filter, for with an inefficient filter there may, when air is re-circulated, be an accumulation of impurities in the building affected. The extension of the work in this section is commended to the interest and backing of the organizations concerned. With the help of the British Electrical and Allied Industries' Research Association experiments were made possible on the ventilation in a room when warmed by different methods.

Among the new apparatus described in the report is a rain gauge, used for experiments on damp penetration, which records the amount of rain received from different points of the compass. There are also described a machine for comparing the slipperiness of different types of floor and an apparatus for measuring the efficiencies of various treatments for minimizing the condensation of water on walls.

RADIO-TELEGRAPHY AND RADIO-TELEPHONY

N the *Proceedings* of the Wireless Section of the Institution of Electrical Engineers of June there a review of the progress made in radio-telegraphy d telephony during the last few years by C. E. ickard of Marconi's Wireless Co., Ltd. As this eriod has been notable for steady advance rather an outstanding invention, he was faced with two ain problems (1) where to start and where to finish relating this progress, and (2) what relative im- ortance to attach to the numerous branches and mifications which together make up the science, t and practice which provide the subject-matter such a review. Progress in the science of radio vers advances of knowledge in theory and technique, but progress in the art, although dependent on progress in the science, also depends largely upon the commercial application of such improvements as may have been made in the past. In addition, the commercial aspect of progress in the art of radio, although mainly controlled by economics, is also governed by the application of international regulations in the practice of radio communication. Seeing that a new international agreement has recently been reached at Cairo, the occasion to discuss the effects of the 1938 convention is opportune.

The recent plenary International Conference to review the Telecommunications Convention, and General Regulations made at Madrid in 1932 was held at Cairo in the spring of 1938. The Conference commenced on February 1 and was opened by H.M. King Farouk at the Heliopolis Palace Hotel. The work of the Conference entailed much study of the business aspects of telecommunication, including telegraph and telephone tariffs, communication procedure, traffic routing, and many other factors in the art and practice of telecommunication in all its branches. It also included a very important item, the revision of the Madrid General Radio Communications in the light of present-day needs, resulting from progress made during the past five years. This progress had led to increasing congestion in the ether, owing to the tremendous expansion of radio services during this period. Of particular importance was (*a*) the growth of aerial transport, of which radiocommunication in all its forms is a most important ancillary service; (*b*) the ever-insistent demands of broadcasting, which have gathered added strength from the increasing weight of public opinion and political activity; (*c*) the further development of the marine services in all branches, but especially in the short-wave trawler telephony and radiogoniometric services.

The actual modifications made at Cairo, although large, were much smaller than expected. These were mainly due to the modifications made in the allocation of frequencies to the various services, and to the tightening up of the regulations in respect to the frequency tolerances, attributable to the various types of transmitter corresponding to the different services they perform.

The first real allocation of frequencies was made at Washington in 1927 and was largely the result of experience gained during the Great War and subsequent years. It was a tentative effort to distribute the available frequencies among the claimants whose services at that time had begun comparatively recently, namely, radiogoniometry, broadcasting, radiotelephony for small ships, short-wave point-to-point services and amateur activities. Th frequency allocations thus adopted were largel influenced by the positions in the radio frequenc spectrum required by these new services. At Madri the frequency allocations were slightly modified t meet growing needs, but the frequencies still remaine allocated in comparatively wide bands which wer shared among various classes of services. This le to crowding in the case of mobile bands the frequencies of which were shared by marine and aircraf services, notwithstanding the fact that the types o apparatus practicable for these very different vessel vary largely in size and weight and consequentl in their technical characteristics. At Cairo furthe efforts were made to facilitate the solution of th problem of the expansion of the aeronautical service by specifying exclusive bands of frequencies to th various aircraft routes at present in contemplatio

The addition of the *Queen Mary* to the mercantil marine has been a milestone from the radio engineer' point of view. This ship is designed to meet th special requirements of vessels of her class for whic it will serve as a model. Developments of the direction finding services have been continuously taking place especially in Adcock direction-finders. The study c traffic requirements and the development of engineering and organization methods hand-in-hand hav enabled excellent services from an economical poin of view between many points on the earth's surfac to be found. Printing telegraph methods employe in submarine cable telegraphy are now also employe for radio purposes. The approach of the next sunspo maximum has enabled the P.O. engineers to provid additional plant and aerials so as to meet the antic pated adverse conditions such as frequency 'wobbling In ionospheric investigations, important theoretic and experimental discoveries have been made. M Rickard concludes by discussing vacuum tubes an high-frequency cables which can now be constructe so as to be semi-flexible.

TYŌKŌ AND HIS SEISMOSCOPE

A. IMAMURA has recently translated relevant passages concerning the life of Tyōkō and his seismoscope from the Chinese history "Gokanzyo" and discusses this very interesting topic[1].

Tyōkō was born in A.D. 78 in Si-o, Nan-yang Province, China, during the later period of the Post-Han dynasty, and held during his life several important governmental posts including that of the director of the Bureau of Almanac and History during A.D. 115–121, and A.D. 126–133. He was an excellent astronomer and a great literary man, and one of his duties besides constructing almanacs and writing history was to record the great events which happened in the country. About that time, parts of China were seismically active, which may account for his interest in seismology. He is said to have invented, in addition to his seismoscope, an instrument resembling in some respects the modern theodolite, a clock, a tricycle, and a so-called self-flying bird.

In the original Chinese history the seismoscope is not figured but only described. J. Milne in his "Earthquakes and Other Earth Movements" reconstructed a figure and gave a description. Imamura corrects some parts of Milne's figure and descriptio and also comments on interpretations by Mr. Wan Chen-to and Mr. T. Hagiwara, and on a seismoscop constructed by himself.

Tyōkō's seismoscope consisted of a pendulu device which caused a copper ball to fall out of on of eight dragon's heads into the mouth of a waitin toad, according to the direction of the epicentre the shock. Imamura states that the central pill was in all probability an inverted pendulum, th no record of the earthquake was made by the instrument, that only one ball dropped at each earthquak and fell into the mouth of a toad, not a frog. In th original description the dimension of the diameter the supporting barrel was given as 8 units. Imamur states that the unit mentioned was likely to have bee one third of a foot whereas Milne took it to be a foo

Tyōkō's seismoscope, invented in A.D. 132, probably being the first seismological instrument, will ran equal with his theodolite in scientific achievemen and points him out as having been a man of geniu He died in A.D. 139 at the age of sixty-two years.

ELECTRICAL PROGRESS IN POLAND

N the *Electrical Times* of August 3, A. G. Moss describes the rapid and confident way in which oland is developing hydro-electric power schemes ithin her boundaries on a long-term basis, and hav-g obviously the utmost confidence in the future. In reat Britain, on the other hand, the tendency at resent seems to be to limit financial forecasts to e next few uncertain months due to possibilities f war.

In a recent tour through Poland, Mr. Moss saw e many plans which are being carried out for arnessing the various sources of industrial power the country for the benefit of the national economic ystem. Although primarily an agricultural country, oland was the last of the great European powers utilize their native fuel and water-power; but ow, for about the last twenty years, rapid progress as been made and this notwithstanding the crippling nancial burden which the Polish army and arms roduction has, of necessity, laid on the country uring this period.

Poland's power resources consist of great coalfields the Silesia, Krakow and Dabrowa regions in the outh-west. In addition there is hydro-electric ower distributed along the rivers of the Carpathian othills, and, a little farther north, vast fields of atural gas which are easily tapped for direct supply r domestic and industrial use. The presence of hese three sources of power might have led, as in ther countries, to harmful commercial competition etween those specially interested in them. In oland it was considered that electrical power was uch the most desirable.

The Polish Government is therefore considering lectrification on a national basis within the next ew years. This presents difficulties when we emember that nearly 70 per cent of the population agricultural and lives at a low peasant standard. evertheless, in spite of these serious difficulties, it going ahead very energetically with this end in iew.

In some parts of south Poland, natural gas is apped straight from fields into the home at a very ow cost to the consumer. In some cases, street amps are left on all day as it is cheaper to let them urn than to pay a man to put them out. Considered rom the national point of view, the Government has ecided that electricity is the most economical ethod to use. In an official document published in Varsaw a few weeks ago it is stated "The Polish epublic and the Polish Government fully realize hat backwardness in electrification must be made ood in the very near future in order to enable due rogress to be made by the whole economic life of he country".

The average increase in the electrical output ver the last six years amounts to nearly forty er cent. In Belgium the corresponding percentage 33, and in France 22. It has to be remembered hat Poland only recovered its present independence in 1919, and spent the next two years de-nding it. This increased demand for electricity as already necessitated large-scale extensions to the olish high-tension zone grid systems and also the onstruction of a considerable number of new electric ower stations.

SCIENCE NEWS A CENTURY AGO

Daguerre's Discovery Described

ON August 19, 1839, Arago at a meeting of the Paris Academy of Sciences "in the presence of a crowded audience, which had besieged the doors of the Institute three hours before the commencement of the sitting, divulged the secret of M. Daguerre's invention, which has now, as you are all aware, become public property. Three drawings having been exhibited by way of Specimens, M. Arago began by capitulating the discoveries—or rather hints towards discoveries, of former chemists; he afterwards dwelt upon the progressive experiments of M. Niepce since carried out by M. Daguerre. . . ." After dealing with Daguerre's process Arago proceeded "to speculate upon the improvements which this beautiful application of optics was capable. . . . The question arose, too, whether it will be possible to take portraits by this method. M. Arago was disposed to answer in the affirmative.

"In physics, M. Arago indicated some of the more immediate applications of Daguerreotype. . . . He instanced some of the complex phenomena exhibited by the solar spectrum. We know, for example, that the different coloured rays are separated by black transversal lines, indicating the absence of these rays at certain parts; and the question arises whether there are also similar interruptions in the continuity of the chemical rays? M. Arago proposes as a simple solution of this question, to expose one of M. Daguerre's prepared plates to the action of a spectrum; an experiment which will prove whether the action of these rays is continuous or interrupted by blank spaces" (*Athenæum*, Aug. 24, 1839).

Completion of Pulkowa Observatory

THE earliest observatory in Russia was built at St. Petersburg in 1725, under the auspices of Peter the Great, and the French astronomer J. N. Delisle (1688–1768) was made director. This observatory was burnt down in 1747, but though reconstructed it remained of minor importance. In 1827 the Academy of Sciences put forward the idea of a new central observatory and three years later the Emperor Nicholas declared through his minister, "that the honour of the country appeared to him to demand the establishment, near the capital, of a new astronomical observatory, conformable to the actual state of the science, and capable of contributing to its ulterior advancement." A site was chosen at Pulkowa, about twelve miles south-west of St. Petersburg, and Fredrick Georg Wilhelm Struve (1793–1864), the director of the Dorpat Observatory, was appointed to superintend the erection of the observatory. "The design of the establishment was upon a scale of unprecedented magnificence. The foundation stone of the building was laid on the 21st of June 1835, and it was finally completed on the 19th of August 1839" (Grant). The instruments installed included a vertical circle and a transit instrument by Ertel, of Munich, a meridian circle and a prime vertical telescope by the Repsolds, of Hamburg, and an equatorial telescope by Merz and Mahler, of Munich. Struve began his observations in September, having among his earliest assistants his son Otto and C. A. F. Peters (1806–80). From its formation the Observatory took a lead in the exact measurements relating to the motion of the earth and the positions of the principal stars, and it was once called "the astronomical capital of the world". The elder Struve retiring in 1861, he was succeeded in the directorship by his son Otto Wilhelm von Struve (1819–1905) and among his successors have been Theodor Alexandrovitch Bredichin (1831–1904) and Johan Oscar Backlund (1846–1916).

The British Association at Birmingham

OWING to the Chartist riots in Birmingham in July 1839, doubts were expressed as to the advisability of holding the meeting of the British Association, but the meeting took place and was successful. On August 24 the correspondent of the *Athenæum* wrote: "Many circumstances combined to throw a gloom over the opening of the Birmingham session of the British Association. The recent disturbances had rendered it doubtful whether the meeting might not be adjourned to another time and place; foreigners were alarmed by the exaggerated accounts of the riots; and the members of the Local Committee, having their attention engaged by the exciting events around them, could not bestow much of their time in preparations for the reception of the Association. Indeed, under the circumstances, it was surprising that their arrangements were so perfect as we found them. Many members, however, were disappointed at the very limited number of manufactories opened to general inspection; and it was thought to be most strange, and a subject of general remark, that no one of the great engineering establishments, for which Birmingham is so renowned, were found in the list. The Local Committee, however, and all who aided them, deserve great credit for their exertions in collecting together the 'Illustrations of Manufactures, Inventions and Models'."

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

LECTURER IN MECHANICAL ENGINEERING at the Hull Municipal Technical College—The Director of Education, Guildhall, Hull (August 22).

DEMONSTRATOR IN BOTANY—The Secretary, King's College, Strand, W.C.2 (August 26).

ASSISTANTS II (Male) in the Meteorological Office—The Under-Secretary of State (S.2.B.Met.), Air Ministry, Adastral House, Kingsway, W.C.2 (August 28).

MASTER TO TEACH MATHEMATICS in the Government Technical School, Baghdad—The Secretary (I.P.R./CA), Board of Education, Alexandra House, Kingsway, W.C.2 (August 28).

A SENIOR SCIENTIFIC OFFICER, A JUNIOR SCIENTIFIC OFFICER, AND AN ASSISTANT I, in the staff for Scientific Research—The Ministry of Supply, Adelphi, W.C.2 (quoting Appts. No. 03/S.E.3) (August 31).

ASSISTANT PROFESSOR OF SOCIOLOGY in the Fuad el Awal University—The Dean of the Faculty of Arts, Giza, Egypt (September 1).

ASSISTANT LECTURER IN ORGANIC CHEMISTRY—The Registrar, University College of the South-West, Exeter (September 9).

VETERINARY INVESTIGATION OFFICER under the Advisory Scheme for the Ministry of Agriculture—The Registrar, University, Leeds (September 13).

LIBRARIAN—The Secretary, Chartered Surveyors' Institution, 12 Great George Street, S.W.1 (September 30).

LECTURER IN PHYSIOLOGY—The Registrar, Municipal College, Portsmouth.

ASSISTANT ENGINEERS for the Posts and Telegraphs Department of Kenya, Uganda and Tanganyika Territory—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/8137).

ASSISTANT ENGINEER for the Drainage and Irrigation Department, Malaya—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/5765).

THE BASIS OF LEADERSHIP

NO more fundamental question is raised in Sir Arthur Salter's stimulating book "Security: can we retrieve it?" than that of the selection and training of leaders in our democratic systems. Many of the dangers to which we are exposed at the present time, he maintains, are the result of defective leadership and not of inherent defects in our democratic institutions. We cannot assume too readily with Prof. Whitehead that the problem is not that of producing great men but of creating great societies, for the great society will put up the men for the occasion.

The present testing time for democracy is forcing us to realize that the two problems are linked inseparably. The question of educating for democracy involves the problems of selection and training for the ever more arduous duties and responsibilities which the growing complexity of the modern State is forcing upon the administrator and statesman. If we have to consider education for citizenship in the sense that the efficient functioning of a democratic system depends upon an intelligent and educated electorate capable of taking independent and unprejudiced views, we have equally to consider it in the sense of providing training which will fit men and women for the many posts in local and central government which under a democracy demand wise judgment, respect for human personality, impartiality and a sense of justice and human values.

The future of democracy may well depend on whether it can put up leaders of the requisite calibre alike in municipal or national affairs, free from party prejudices and capable of taking long views and resolute action. We are being driven to consider again the Platonic view of education—whether, in fact, our system of education should not include some special provision and training for those destined to carry the responsibilities of leadership and administration. The question of a ruling class has once again to be faced fairly and dispassionately.

This is the central problem which Mr. J. M. Murry has raised in a stimulating little book recently published*, and he insists on the necessity of a moral basis for leadership. It is indeed to the separation of religion from the social tradition of Christianity and the acceptance of the complete secularization of society that he attributes a large measure of responsibility for the dangers and difficulties which confront us to-day. There is a striking parallel between the absorption of the Puritan in private religious observances and its consequences, and the absorption of scientific workers in their own special branch of knowledge and their neglect of, or indifference to, the social consequences of their work Both alike impoverish and cramp man's capacities and experience. Mr. Murry makes a passionate attack on the departmentalization of life from the religious side, an attack which should assist as much in bringing science and religion and ethics into that harmony so essential for man to regain his control over events as do the increasing efforts of leading men of science themselves to raise their fellows to a sense of their social and moral responsibilities, of which Sir William Bragg's Pilgrim Trust Lecture before the United States National Academy of Sciences provides a recent admirable illustration.

Mr. Murry argues that, broadly speaking, there are two educational systems in Great

---

*The Price of Leadership. By John Middleton Murry. Pp. 190. (London: Student Christian Movement Press, 1939.) 5s. net.

Britain. The first includes the education of the elementary school, that of the secondary school and finally university education, mainly scientific or technical. The second system, which begins with the preparatory school, and is followed by the public school and then by the university, leads to positions which can only be adequately described as those of the ruling class. Roughly it is true that the ruling class in the main receives a type of education entirely different from that of the rest of the people, and whereas the first system is almost exclusively an intellectual system, in the second intellectual values are definitely subordinated to training in character.

Mr. Murry considers that however lop-sided the public school system of values may be, it is much more realistic and effective than the system of values which prevails through elementary and secondary education, and that the insistence on its codes and traditions as more important than mere intellectual distinction makes for a real social coherence. He is accordingly concerned that we should attempt to preserve its virtues and to incorporate the public schools into the State system in a way that would render them no longer the preserve of the rich. He would achieve this either by bodily incorporating them into the State educational system and by drafting off to them boys who showed proof of a generalized rather than a specialized intelligence, or by founding at least two dozen State public schools which should take over the boy as completely as he is taken over by the existing public schools but should set themselves much more determinedly to discover the boy's real aptitudes.

The fundamental premiss in Mr. Murry's argument is that we should recognize both the existence and necessity in a democracy of a ruling class, and concern ourselves with the education by which a ruling class is formed. The necessity for a class of men educated and trained for administration is widely recognized in industry to-day, where the future of large-scale industrial combines and of the public utility corporation may well depend upon its solution, and less widely in modern society generally. The idea is inherent in the many discussions which have taken place in the last twenty years regarding the place of the scientific or technical expert in administration, and in such reports as that of the Departmental Committee on the Qualifications, Recruitment, Training and Promotion of Local Government Officers.

None the less, even those who are most alive to the social implications of the industrial combine of the public utility company are frequently blind to what is involved in the provision of leadership, and the reception given to the report on recruitment of local government officers indicates how far we yet are from appreciation of what is involved even in training for local administration.

This position is doubly dangerous. It undermines the efficiency of democracy by making it more difficult to secure and operate the regional planning of services such as health, transport, water supply, etc., which are becoming more essential in the general interest and may be vital as defensive measures in war time. Moreover, it hinders the linking of social privilege and social responsibility which has been so marked a characteristic of the development of the democratic system in Great Britain, and is more than ever essential if respect for human personality is to be preserved in the face of totalitarianism.

Mr. Murry indeed writes scathingly of many who profess to be leaders of democracy, and he demands clear and fundamental thinking on the two-party system and democracy as a whole to-day. What he is concerned to find is a system of education which will provide, not merely technically competent leaders, but also leaders who will safeguard for us the great values we have inherited. It is this view of life as a whole, in which moral and ethical no less than social, scientific, technical and artistic elements are respected and blended that leads him to place his main emphasis on the recognition by Christianity of its social relations and implications.

Already in other countries a new ruling class is coming into being, and the need in Great Britain is immediate. The character of the State is determined by the conception of its social responsibilities held by the ruling class. It can select, and under totalitarian impulses it does select, the elements of man's lower nature for embodiment in the character and purpose of the whole social order. Under Christian impulses it can equally reconstruct the State to serve the highest ideals of which humanity is capable. The choice made by the ruling class is determined by the training given to the minds of its members in the schools.

Mr. Murry asserts that the acceptance in Great Britain of State action solely as a channel of personal advantage without any philosophical or religious conception of the State as representative of the higher selves of man to whom duties are primarily owed, has left the moral initiative in

Europe to the new totalitarian nations. The conception of the State as the instrument by which a democratic society is educated to the knowledge of its own nature and purpose is, however, a Christian conception, and Mr. Murry clinches his argument by contending that the religious basis of social life at which he aims can be realized in the schools, and was realized by Dr. Arnold and others. Moreover, when the new industrialists entered the ruling class, they found that individualistic morality was insufficient, and from their ranks came the leaders of a new movement towards a social religion able to meet Marxian materialists on their own ground.

For Mr. Murry democracy cannot exist without Christianity. Unless democracy is constantly revivified by the regeneration of its individual members by Christian education, it must degenerate into totalitarianism. Either the individual must learn to conquer his lower self and attain his true personality as a citizen of a Christian society, or the democratic State, abandoned to be the instrument of the lower selves of its members, will enforce upon him a uniformity which is destructive of his whole personality. "A modern industrial and democratic society by reason of its economic complexity, cannot suffer itself to become anarchical. If it is not permitted to develop creatively into a Christian society it must become a totalitarian tyranny." Like Sir Cyril Norwood in his suggestive address last year on the relevance of Christianity in the modern world at the conference for young public schoolmasters, he claims that national education should be frankly based on Christianity conceived broadly in terms of the spiritual values of truth, beauty, and goodness—values which are increased by being shared.

With very much in Mr. Murry's argument scientific workers will find themselves in real sympathy. They are profoundly concerned with all that makes for the maintenance of freedom of thought, of speech and of investigation and the preservation of spiritual values. Respect for human personality should be as cardinal a principle with them as loyalty to the truth and disinterested search for the facts. In their growing concern for the social consequences of their work they are conscious that, as Sir William Bragg pointed out, in his Pilgrim Trust Lecture, the spirit in which knowledge is sought and the manner in which it is used may be more important than knowledge itself. They themselves have to supply the natural knowledge for a solution of the problems of society, and help in its application. Their effectiveness depends equally, however, on their moral influence, on the devotion, wisdom and good will which they bring to their task. They may well be grateful to Mr. Murry for the clarity with which he displays the moral issues, for the force of his challenge to discard cant about democracy and to think out all that is involved in the training and selection of leaders for democracy not merely as we know it to-day, but as it might be in an ideal society. Nor should they forget that such fundamental thinking will point the way for them to make their own contribution to leadership and to secure the more effective utilization in the service of the community of the knowledge already available and increasingly being placed at its disposal.

STATE-CRAFT AND MEDICINE

The Building of a Nation's Health

By Sir George Newman. Pp. xiv + 479 + 8 plates. (London: Macmillan and Co., Ltd., 1939.) 21*s*. net.

SIR GEORGE NEWMAN, until recently Chief Medical Officer of the Ministry of Health and of the Board of Education, in a preface to his latest work, entitled "The Building of a Nation's Health", states that he intends it to be a "summary record of how statecraft and medical knowledge took council together at the opening of a new epoch of preventive medicine". From one point of view this admirably describes the task which the author has so excellently performed. The responsibility for building and maintaining health in Great Britain may be said to be shared between the medical profession, the State, and the individual citizen. The part of the last named, though it is of essential importance and though it may even be obscured by some activities of the other two agencies, is not dealt with in Sir George Newman's book. This is legitimate, for the responsibility of the individual for his own health, and therefore to some extent for the common health, is somewhat apart from that of those other agencies, and may well be approached from a different angle and separately described or enforced. The responsibility of the State and of the medical profession cannot, however, be so dissevered; and, indeed, one of the main features of Sir George's book is the clearness with which it brings out, and the force with which it emphasizes the unity of the field of medicine, and the need for the intimate co-operation of various bodies of persons within the wider field of health. This leads one even to hope that the phrase "preventive medicine", however convenient when carefully used, may be abandoned wherever possible, and the phrase "the preventive aspects of medicine" used in its stead. For "preventive medicine" cannot be separated either from "curative medicine" on one hand or from "constructive medicine" on the other. It is false to regard the State as being concerned with prevention and the medical profession with cure, or one class of medical practitioner as dealing with the former and another class with the latter. These are merely aspects, and not very clearly defined ones at that, of something which is essentially a unit.

It is but little more than a century since the State began to realize its responsibility for the public health and actively to exercise its functions in relation thereto. During that century, and especially during the last thirty-five years or so, it has taken a constantly widening and more serious view of these responsibilities and functions. It was at first concerned, and is still perhaps primarily concerned, with environmental factors and the control of epidemic disease; but it is now enlarging its conception even of these so that the nutrition of the people and the opportunities for physical exercise and training are now regarded as its business. Further it has interested itself in the better education, regulation, and organization of the medical profession, and of ancillary health workers, so that their services may be more easily available for the public and more effective when used. It has brought medical advice and treatment within the means not only of the very poor but also of every worker, and has provided medical attention for other classes of the population and for certain abnormal conditions or diseases of more than ordinary communal importance. It is the whole of this field which Sir George Newman surveys in his book. No other person could have done it so appropriately, so comprehensively, or so well. It is not only that he has held positions in the public service which have afforded him unrivalled opportunities for knowing or observing almost every movement in this extensive sphere, but that he himself, in those positions, has been a motive, a controlling, or a directive force during twenty-five years or more of official life. Moreover the interested public has long recognized, through his series of annual reports as Chief Medical Officer to the two Government Departments most concerned with health matters in England and Wales and through his other writings, that he has a faculty of marshalling and setting out his material, and of attractive statement of facts and expression of ideas and opinions which add to the value of what he has to say and commend it to his readers. All these qualities are evident in his latest book, which, though it is to be hoped that it is not his last, may be regarded as his most important contribution to an understanding and appreciation of the national movement towards health with which he has been associated.

Very properly, and with evident deliberation, Sir George Newman places the medical profession in the forefront of the picture. He traces its governance and regulation through the Medical Acts and the General Medical Council, expounds recent movements and the new spirit in medical education, and discusses the status, duties, and privileges of medical officers and private practitioners in relation to communal requirements and public authorities. "Nothing is more remarkable," he says, "in the history of the public medical service in Britain, than the great and continuing contribution made by the medical practitioner." The delay by the State in making use of these contributions cannot fail to be noted. There is a lag between the acquirement of knowledge by research and the application of this knowledge in actual medical practice. There is a further lag between this application and the action of the State towards making it more easily and widely available. This is natural enough, and may even be advantageous, provided the lag is not too great, and that it is not due to professional negligence, obstruction, or claims to the sole occupancy of fields which are not wholly medical.

Next in importance to medical work and influence in the building of the nation's health has been that of voluntary societies and movements. This is shown in almost all the chapters in which the various public health services are surveyed. Thirdly comes the influence of certain great personalities, both medical and lay, to whose initiative and activities the author pays tribute. It is well that the public should be reminded of these men and informed, even though very succinctly, of their life and work. There are portraits of some: Sir John Simon, Medical Officer of Health, City of London, 1848–55; Sir Donald Macalister; Sir William Osler; Sir Robert Philip; and Sir Robert Morant. Sir George Newman's book is alike an interesting history, a guide to the principles which should influence future developments, and a work of reference. The volume should be welcomed as one of much importance and value.

THE THEORY OF NUMBERS

An Introduction to the Theory of Numbers
By Prof. G. M. Hardy and Prof. E. M. Wright. Pp. xvi+404. (Oxford: Clarendon Press; London: Oxford University Press, 1938.) 25s. net.

THE theory of numbers has an appeal to general interest, not shared by other branches of mathematics, in that most of the great unsolved problems of the subject are formulated in terms intelligible to everybody. There must be many people of limited mathematical attainments who have felt attracted to the subject, but whose interest has died away for the want of just such a book as this to stimulate it.

The point of view from which the book is written can best be described in the authors' own words.

> "It is not in any sense (as an expert can see by reading the table of contents) a systematic treatise on the theory of numbers. It does not even contain a fully reasoned account of any one side of that many sided theory, but is an introduction, or a series of introductions, to almost all of these sides in turn. We say something about each of a number of subjects which are not usually combined in a single volume, and about some which are not always regarded as forming part of the theory of numbers at all. . . . We have often allowed our personal interests to decide our programme, and have selected subjects less because of their importance (though most of them are important enough) than because we found them congenial and because other writers have left us something to say."

There can be no doubt that the authors have carried out their programme with marked success. In spite of their modest disclaimer, the book is really as systematic as any elementary account of so extensive a subject can be, or ought to be. It presupposes, for the most part, no more knowledge of mathematics than is possessed by a first-year university student, and yet it introduces the reader to almost all branches of the theory of numbers, including some which have only been developed in recent times. Naturally, in some branches, the deeper results have to be stated without proof; but the book does contain proofs of practically all theorems that are genuinely elementary (using the word in its non-technical sense). Mathematicians of all kinds will find the book pleasant and stimulating reading, and even experts on the theory of numbers will find that the authors have something new to say on many of the topics they have selected.

The selection of topics, and the general approach to the subject, have a slight analytical bias, as will be seen from the list of contents. The reader is introduced at the outset to the O, o and $\sim$ notation of modern analysis, and later to the notions of 'almost all integers', 'sets of measure zero', and 'uniform distribution'.

Each chapter is a model of clear exposition, and the notes at the ends of the chapters, with their references and suggestions for further reading, are invaluable. The only points in the book which the reviewer feels any inclination to criticize are (1) the section on integral quaternions, where the exposition of Dickson has been preferred to the more elegant theory of Hurwitz; (2) the definition of a convex area, which is obscured by the mention of a convex *curve* (a convex area or body is a much simpler thing than a curve, let alone a simple, closed, continuous curve); (3) the absence of an explicit theorem on the existence of primitive roots (mod p).

The printing is excellent, and has not that squashed appearance which is such a common fault of present-day English mathematical printing.

In the following summary of the contents, chapters which deal with the same side of the subject are grouped together.

Chapters i, ii, xxii (first half): the series of primes. A fairly complete account of what is known and what is conjectured about the distribution of the primes, with proofs where these are of an elementary character.

Chapters v, vi, vii, viii: congruences. The classical elements of the theory of numbers.

Chapters iv, ix, x, xi, xxiii: Diophantine approximation. Accounts are given of decimals and continued fractions, proofs of the transcendence of e and π, and three proofs of Kronecker's theorem.

Chapters xii, xiii, xiv, xv: quadratic fields. A few particular fields are treated, and the field $k(\sqrt{-3})$ is used to prove the insolubility of the equation $x^3 + y^3 = z^3$ $(xyz \neq 0)$.

Chapters xvi, xvii, xviii, xxii (second half): arithmetical functions. The formal properties of various arithmetical functions are considered, together with the associated Dirichlet series, also the order of magnitude, average order of magnitude, and normal order of magnitude of some of them.

Chapters xix, xx, xxi: additive theory. One chapter is devoted to partitions, one to representations by two or four squares, and one to Waring's problem. The chapter on partitions is one of the most attractive in the book.

Chapters iii, xxiv: geometry of numbers. Minkowski's theorems on lattices and linear forms.

H. DAVENPORT.

STATISTICAL MECHANICS: ANCIENT AND MODERN

The Principles of Statistical Mechanics

By Prof. Richard C. Tolman. (International Series of Monographs on Physics.) Pp. xix + 662. (Oxford: Clarendon Press; London: Oxford University Press, 1938.) 40s. net.

NOT so long ago, statistical mechanics was almost synonymous with the somewhat arid topic of the dynamical theory of gases, but the development of the quantum theory has vastly increased the number of subjects which can be treated by statistical methods. Nowadays statistical mechanics deals with the properties of matter in its widest sense, and there has been a steady stream of books concerned with the applications. But although the great development of the subject has been mainly due to the success of the quantum theory in dealing with the interactions of atoms and to the introduction of the Fermi-Dirac and Einstein-Bose distribution functions, yet the repercussions upon the foundations of statistical mechanics have been not less important. So far this part of the theory has been almost completely neglected; Prof. Tolman's important book is meant to fill this gap, and it leaves off where most books begin. The word "principles" in the title of the book does not mean that the book is an introduction to the subject—far from it—but that it is concerned with the logical development of the fundamental principles.

The student of the foundations of statistical mechanics has always been in a rather difficult position. The subject is by no means an easy one, and the presentations given in the classic treatises differ so widely that it requires profound thinking to be able to see that they refer to the same subject. Further, there is no systematic account of the foundations of quantal statistical mechanics (the topic is dismissed in a few pages in the modern treatises on the applications), and the student usually gives up the task of reconciling the various accounts and contents himself with learning to use the distribution laws and to calculate partition functions.

Of the various possible ways of developing the subject, Prof. Tolman adopts that favoured by Gibbs, and discusses the properties of ensembles of systems. This has the advantage that the treatment of quantal statistical mechanics is analogous to that of classical statistical mechanics; indeed in the book the classical theory is given in Chapters i–vi and the quantal treatment in Chapters vii–xii, corresponding chapters having almost identical titles. Now, although Gibbs's method is most satisfying to pure mathematicians in that all the necessary assumptions can be very easily introduced and the whole theory developed in a very logical manner, yet it has always seemed to many physicists to lack that physical plausibility which gives a feeling of life to a subject. Gibbs himself gives to the not too inquiring reader the feeling that statistical mechanics is not concerned with real things. For example, the only justification which Gibbs gives when introducing the canonical distribution ("Elementary Principles in Statistical Mechanics", p. 33) is that this distribution "seems to represent the most simple case conceivable, since it has the property that when the system consists of parts with separate energies, the laws of the distribution in phase of the separate parts are of the same nature—a property which enormously simplifies the discussion, and is the foundation of extremely important relations to thermodynamics". He does indeed show later on, almost at the end of the book, that the familiar thermodynamic equations can be derived from his statistical mechanics, but to many physicists this is very like putting the cart before the horse; they feel that a better procedure is to put thermodynamics right in the forefront of the theory and to deduce the statistical temperature and entropy in as direct a manner as possible. This method of exposition, however, often loses much of its force because the empirical temperature is taken as an intuitive idea instead of being defined thermodynamically as a function of the state of a body which is the same for all bodies in thermal equilibrium with one another. In the reviewer's opinion, the ideal exposition would be one in which this latter more physical approach is introduced at the beginning, while Gibbs's method is used for the subsequent developments.

Those of the 'physical' school of thought will feel regret that Prof. Tolman has chosen to follow Gibbs, but it will be regret tempered by pleasure in that Prof. Tolman's exposition goes a long way towards removing many of the objections to the method. As one example of this we may quote the full discussion of the relation between the canonical and the micro-canonical ensembles and of the justification for using the canonical ensemble. The plan of the book is as follows. Part 1 deals with the classical theory, and, after chapters on the Hamiltonian theory of general dynamics and on statistical ensembles, the Maxwell distribution aw is derived and Boltzmann's H-theorem is proved. The discussion of the latter topic is much more detailed and precise than is usually given.

Part 2, on the quantal statistical mechanics, is the most important part of the book. It is, however, marred, in the reviewer's opinion, by the inclusion of an exposition of quantum mechanics occupying about 150 pages. Most of this is quite irrelevant, breaks the continuity of the book and expands it into a volume which is too bulky. There would perhaps have been a good deal to say for the inclusion of some general theory starting from a fairly advanced point, since some of the results required are not readily available in a convenient orm, but discussions of such topics as one-dimensional collisions and the hydrogen atom are quite out of place. The writer of a book such as this must assume that his readers are well versed n the elements of quantum mechanics and, in all probability, in the more advanced theory also. If they are not, they will find the going rather heavy. As in Part 1, the main objects are the derivation of the distribution functions and the proof of the H-theorem. Part 3 deals with the relation of statistical mechanics and thermodynamics.

The book has been most carefully and, for the most part, well written, but the reviewer found himself sometimes fogged by the wealth of explanation. In dealing with a difficult subject, it is by no means easy to know how much explanation to give, since over-exposition is almost as bad as under-exposition, but the book would probably be improved by being shortened. It is, however, a valuable addition to the literature, and will be indispensable to those who wish to understand the principles of statistical mechanics, especially of quantal statistical mechanics.

A. H. W.

GROWING-POINTS OF ORGANIC CHEMISTRY

The Chemistry of the Carbon Compounds
By Victor von Richter. Edited by the late Prof. Richard Anschütz. Vol. 2: The Alicyclic Compounds and Natural Products. Translated from he twelfth German edition (compiled by Prof. A. Butenandt, Dr. M. Lipp, Dr. K. Niederländer, Prof. F. Reindel and Dr. F. Rochussen) and evised by T. W. J. Taylor and Dr. A. F. Millidge. Third edition. Pp. xiii+656. (Amsterdam: N.V. Uitgevers-Maatschappij "Elsevier", 1939.) n.p.

IN his introduction, Mr. Taylor explains that this book is a translation and revision of the first part of volume 2 of the twelfth edition of Richter-Anschütz's "Chemie der Kohlenstoffverbindungen", he German original of which appeared in 1935. The closely related fields of work here selected for treatment are of the first importance in modern rganic chemistry. Section A, comprising about 50 pages, deals with alicyclic compounds, and iscusses in the first instance such fundamental matters as the formation and stability of ring structures, ring transitions, and general methods f preparing alicyclic compounds. The detailed consideration of monocyclic compounds is then taken up, ranging systematically from the *cyclo*-propane group to compounds containing 34 carbon atoms in the ring. The succeeding description of polynuclear alicyclic compounds embraces rings directly united and those separated by a chain, spirane structures, condensed cyclic systems, and bridged rings. Terpenes and resins are then treated under the headings of olefinic terpenes, monocyclic terpenes, bicyclic terpenes, and sesquiterpenes and polyterpenes.

Section B, comprising the rest of the book, is devoted to the successive consideration of various classes of important naturally occurring compounds, including glycosides, tannins, lichen acids, the active principles of the peppers, natural colouring matters, nitrogen-free poisons, sterols, bile acids and scymnol, vitamins, and hormones.

In the preparation of this valuable edition the original authors revised their contributions to the German edition, and the English translation was subjected to a final revision by Mr. Taylor and Dr. Millidge, with assistance from Prof. A. R. Todd, Dr. S. G. P. Plant, and others. The result is a reliable and surprisingly detailed and up-to-date account of a vast and ever-growing region of organic chemistry. So far as the reviewer has put the text to the proof, the important advances of the last few years in these many fruitful fields of endeavour find here an admirable presentation. As a compact and yet comprehensive work of reference the volume will be of outstanding value to specialists and research workers in the many subjects of which it treats. The continued references to the *Zentralblatt* which formed a somewhat irritating feature of earlier editions of Richter-Anschütz have been happily replaced by direct references to the original papers, including the names of the authors. The text and formulæ are well printed, and there is a good subject index of fifty pages.

John Read.

THE MORPHOLOGY OF THE FLOWER

Floral Morphology

A New Outlook with Special Reference to the Interpretation of the Gynæceum. By E. R. Saunders. Vol. 2. Pp. xiv+133–609+vii. (Cambridge: W. Heffer and Sons, Ltd., 1939.) 10*s*. 6*d*. net.

THE first volume of Miss Saunders's review and summary of her studies on floral morphology was published in 1937 and was reviewed in NATURE of July 24, 1937, p. 132. The second volume is much larger in size and higher in price. Its pagination continues from that of volume one.

In the first volume the author outlined the essential structure of the flower and explained the theory of carpel polymorphism. This, with various consequences of its acceptance, was exemplified by details of a limited number of families (thirty-nine) and selected genera within the families. The general aim was "to serve as a guide to the study of types in the laboratory".

The second volume brings the number of families described up to 190, that is, the vast majority of families of Angiosperms are considered in greater or less detail. The families were, in the first volume, arranged in a sequence adapted to a scheme of laboratory work; in the second volume the arrangement is more taxonomic. The taxonomist would have preferred that the sequence throughout had been according to one of the widely recognized taxonomic classifications. The inclusion of what appears to be a very adequate index largely recompenses for the peculiarities of arrangement.

Miss Saunders has, since 1923, published a large number of papers dealing with floral morphology and especially with that of the gynœcium. She has emphasized the relation of the vascular ground-plan to the floral ground-plan. The fundamental principles of her interpretations are briefly recapitulated in a two-page introduction to the present volume.

Typically and most simply a single vascular bundle turns out from the central cylinder of the axis, traverses the cortex, and is continued into the corresponding floral member as the midrib. Lateral branching may or may not follow or precede exertion. Thus there depart from the central axial cylinder bundles corresponding in number and in radial disposition with the number and arrangement of the floral members. Owing to space conditions of the short receptacle, fusion, breaking-up, degeneration, or loss of vascular strands may occur and result in complications, yet "the formation of whorls of midrib bundles and their correspondence with the whorls of floral members is a fundamental feature of floral construction and the fact that these midrib bundles originate on definite radii provides a means of determining the number of members in a whorl".

A study of the vascular system of flowers, together with a consideration of various morphological features, many of which have long been known and have puzzled morphologists, led Miss Saunders to accept and expound the theory of carpel polymorphism. In an appendix (pp. i–vii), under the title "A Century's Challenge to Orthodoxy in Ten Chapters", she shows that various botanists had long ago proposed, at least for special or limited groups, interpretations of flower structure definitely or by implication in agreement with the theory of carpel polymorphism.

A very great deal of the present volume is quite 'orthodox'—is indeed descriptive in the ordinary taxonomic sense. The theory of carpel polymorphism is, at present, heterodox, but has now been so lucidly stated with a wealth of examples that floral morphologists who remain orthodox, or who favour some other heterodoxy, must feel they have to meet a challenge worthy of their best efforts.

The need for a reconsideration of morphologica concepts and terminology, especially of the flower is now widely recognized, partly owing to Mis Saunders's own published researches. If agreement could be reached among morphologists and anatomists on the interpretation of the major fact there is no doubt that the conservative taxonomis would, in time, revise his descriptive methods. A present he is somewhat confused by a multiplicity of views. He is told, by different authors, tha carpels are leaves, that they are branches, tha they are organs *sui generis*, that they are all o one kind, that they are of several kinds, or even that they do not exist. For the present, th taxonomist would be wise to use, so far as i reasonably possible, only neutral terms and phrases, that is, descriptive terms and phrases th use of which does not imply acceptance of any 'explanatory' theory.

It is somewhat disappointing that in this volume Miss Saunders has not published an account o the relationships between the theory of carpe polymorphism and floral evolution. It would be nteresting if she could connect up divergence of carpel form with possible phylogenetic lines and developmental tendencies. Does carpel polymorphism help in interpreting 'convergence', 'parallelism', 'reticulation' and other supposed modifications of what is often considered the ideal type of phylogenetic tree? Does the theory support the view of a monophyletic origin of the Angiosperms? Does it give new or detailed suggestions as to the nature of 'primitive' carpels? Again, it is probable that in the course of her work Miss Saunders found cause to criticize not only the morphology but also the taxonomy of the taxonomist. He would welcome her criticisms. There really seems to be a need for a third volume of floral morphology.

W. B. Turrill.

INTRODUCING HUMAN ANATOMY

The Tissues of the Body

An Introduction to the Study of Anatomy. By Prof. W. E. Le Gros Clark. Pp. xi+372. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 15s. net.

Of late years there has been a rather depressing spate of books that purport to be introductions to the study of anatomy. For the most part these works tend to recapitulate the type of book that was formerly addressed to nurses or students of massage but which is now dished up for the benefit of the medical student. As such they are symptomatic of what in the United States has been termed "the eclipse of Anatomy" and are the outcome of the present tendency to abbreviate the medical student's course in the study of human anatomy. They can only be classed as the products of expediency in a period during which the teaching of anatomy to medical students is definitely undergoing eclipse. If the student is to have his study of anatomy curtailed n an overcrowded curriculum it is but natural that the text-books read by a former generation may prove to be beyond his capacity and his needs.

It is merely a question of relative values. There are those who still fancy that the time devoted to anatomy by the student of some forty years ago was not altogether wasted in the education of a practitioner of medicine.

There are those who think that some three hundred hours are sufficient for learning as much of the intricate structure of the human body as is necessary for one who is afterwards to treat the derangements of this complicated structure. Maybe there were those of an older generation who attached too much importance to the minutiæ of structure and a swing back of the pendulum is but natural. In any event, we have to realize that the present tendency is to reduce the time devoted to the study of anatomy and so to render, for the medical student, the older masterpieces of descriptive anatomy redundant in his library. It is this state of affairs that has produced a host of minor books to meet the lessened need of knowledge demanded from the medical student: and these books are mostly the products of authors to whom the production of a more complete and authoritative work would prove a matter of some embarrassment.

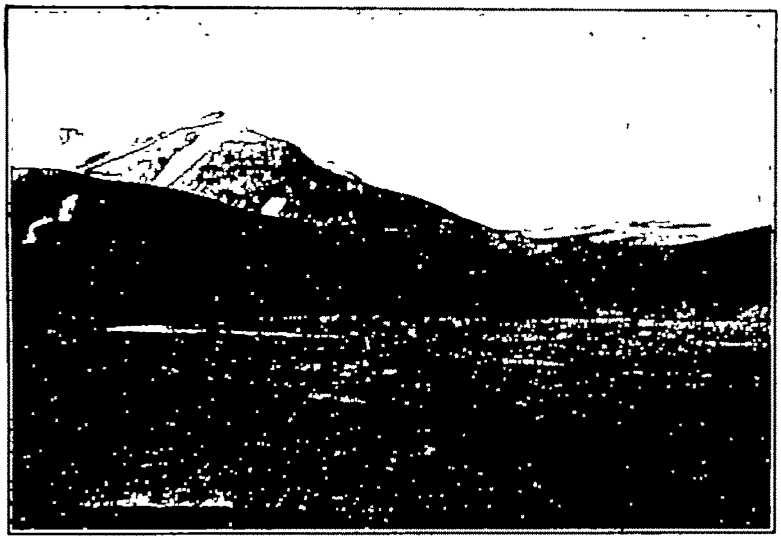
It is therefore an occasion of some satisfaction to meet with a book, written designedly as an introduction to the study of human anatomy, that does not presuppose a lowering of the standard of the student's knowledge and one that is written without an eye to minimum requirements in the medical curriculum and in the examination room. Moreover this book is not the product of one to whom the production of a mere introductory handbook could be pictured as the maximum scientific enterprise. Prof. Le Gros Clark has, in this volume, adopted an almost Hunterian outlook, and in reading his book one is tempted to think that it is only a matter of time before another British anatomist pays open homage to an older tradition in British anatomy and so helps in a renaissance—long overdue—that would end the period of "the eclipse of Anatomy".

The "Tissues of the Body" is not a work on histology, for Le Gros Clark, like Bichat, treats of tissues as the basis of animal organization: moreover he treats of them, so far as present knowledge permits, as living and functional elements. It may be permitted for a reviewer to regard this book as one of the most welcome contributions that has been made to the science of anatomy for many years and to express the hope that it will replace, on the shelves of the medical student's library, several minor works that at present appeal to him under the guise of being introductions to this subject.

F. Wood Jones.

ARCTIC PLANTS IN THE BRITISH ISLES

By Dr. Nicholas Polunin, Herbarium, University of Oxford



[*N. Polunin.*

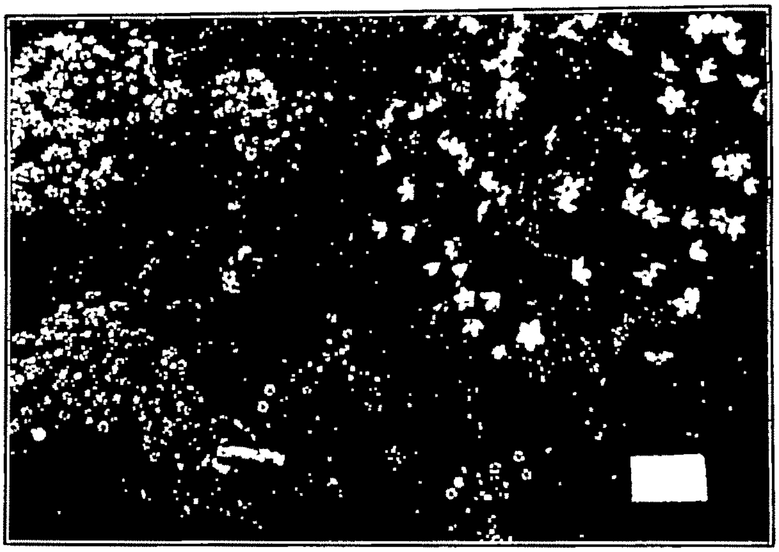
Typical arctic terrain in summer: an inland valley in Spitsbergen. Perennial patches of snow are frequent almost to sea-level, a tongue of glacier being visible in the distance on the right. The ground is stony and 'barren' except in especially favourable situations, where tracts of marsh or heath may develop, as in the foreground and around the grazing reindeer in the centre

IT is well known that, after the final retreat of the Pleistocene ice in western Europe, the flora of the British Isles was for a time much more like that of the arctic regions of the present day than is now the case. The same must be true of the vegetation and its component plant communities. Following the subsequent amelioration of climate, there came waves of relatively mesothermic dominants before which the smaller and less aggressive microthermic species retreated. The picture is clear and our knowledge of the story seems sufficiently complete. But we still do not know what proportion of the present British flora persisted through the Pleistocene maximum; nor have we investigated the mechanisms which enabled certain plants of 'arctic' affinity to survive in Britain to the present day. My object here is to deal with aspects of this latter problem—in a manner which I would scarcely dare attempt if I had not spent much of the last decade in various arctic and subarctic lands—first by deciding which plants are to be considered as truly arctic and then by analysing the resultant list of species.

It has always seemed to me that the so-called arctic element in the British flora is grossly exaggerated, since it is allowed to include many species which, even if they persist far north of the Arctic Circle, do so only in regions which are unusually favourable in climate and often actually forested—hence not really arctic at all. A fairer criterion would be to take such a line as the southern limit of the 'outer arctic zone', within which the mean temperature of the warmest month does not normally exceed 5° C.; and since this line in general lies around the 75th parallel of latitude I have taken this parallel as the least unsatisfactory principle of delimitation in the present instance. The result is that my arctic species are in most cases the

[*N. Polunin*

An arctic sea coast: Devon Island in northernmost America. In the foreground a glacier is discharging into the sea. Behind are poorly vegetated coastal plains and hills with perennial patches of snow



[N. Polunin.

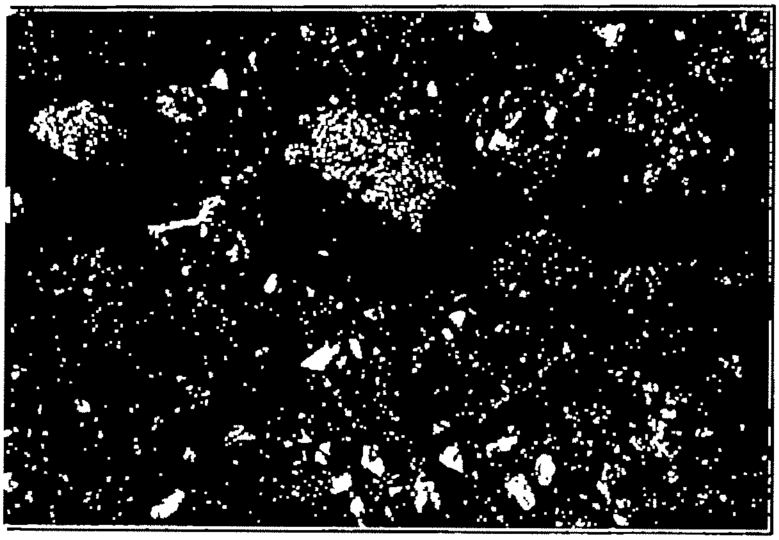
A manuring effect: dense mossy sward including *Saxifraga caespitosa* (on left) and *S. Hirculus* (on right) developed around the nests of wildfowl even in exposed and otherwise barren places, and indicating that a lack of nutrient salts is one of the chief factors inhibiting plant growth in the Arctic. The scale is shown by matchbox.

'high-arctic' ones of other authors—whose attempted subdivision of the element according to the supposed history and place of origin of the individual species ought probably to be shelved pending further research.

Altogether, sixty-two species or geographical varieties of vascular plants in the native British flora are now known to persist north of the 75th parallel of latitude and hence to be truly arctic. This is an addition of five (which *just* qualify) to the number of my preliminary analysis[1]; it does not include such aggregates as *Cardamine pratensis*, *Arenaria ciliata*, *Saxifraga stellaris*, *Chrysosplenium alternifolium*, *Matricaria inodora*, and *Carex salina*, which are represented in the north only by a variety that is subspecifically distinct from any form occurring in Britain, and which may accordingly be expected to have different ecological relationships in the two regions. The lower cryptogams present rather different problems and, being moreover much less known as regards distribution, seem best ignored for the present reckoning.

These sixty-two truly arctic vascular plants occurring in the British flora are all perennials. Many of them reproduce chiefly by vegetative means—a tendency which becomes more and more apparent the farther north we go. Classification of the sixty-two according to their most characteristic habitat in Britain, which is almost always comparable if not identical with that occupied in the Far North, gives the following categories and figures.[2]

1. *Plants of Open Soil or Rock Crevices*—competition generally negligible whether conditions are predominantly dry or damp. (*a*) Of general arctic distribution including high latitudes (*c.* 80° N.). This category comprises twenty-five species, of which three are frequently to be found also in closed communities. (*b*) Of fairly wide arctic distribution (for example, North Greenland and Ellesmere, or Spitsbergen and Novaya Zemlya). These are represented by eleven species, of which two are frequently to be found also in closed communities. (*c*) Extending far north only in Spitsbergen—tempered by Gulf Stream. Represented by four species, making a total of forty characteristic of open soil or rock crevices.



[N. Polunin.

An arctic 'compass plant': *Silene acaulis* in northern Spitsbergen flowering so regularly on the south-facing side of its domed tussocks that it enables a careful traveller to keep a very good 'line'. The boundaries of the non-flowering parts of the tussocks have been inked over. Note the lack of plant-covering on most of the ground.

2. *Plants of Seashore and Lake Margins*—community open, competition again at a minimum. In these habitats are found seven species or varieties which are common to the British Isles and

the Arctic, making a total of forty-seven characteristic of open habitats.

3. *Plants Characteristic of Other Habitats* but frequently found in open areas in both north and south. Of these there are eight species, making a total of fifty-five which are to be found in open areas.

4. *Marsh or 'Heath' Plants.* Of these there are seven species.

The more important conclusions to be drawn from these statistics are as follows: an overwhelming majority of the sixty-two native British vascular plants which reach high latitudes grow chiefly in the absence of competition—both towards their northern limit where the vegetation is generally open and towards their southern limit where under natural conditions it is almost always closed. No fewer than forty-seven (75·8 per cent) are plants predominantly of open soil (or rock crevices, which are ecologically similar in that competition is generally lacking), another eight being frequently found in such situations both in the north and in the south (total 88·7 per cent).

Of the seven remaining plants (which are rarely if ever to be found in open areas in the British Isles) I have seen one (*Eriophorum angustifolium*) colonizing damp open soil in the Far North both in Spitsbergen and Ellesmere, and to the south in Iceland, Labrador and southern Greenland; the larger phase of temperate regions may well be taxonomically as well as ecologically distinct. Exactly the same remarks apply in the case of *Calamagrostis neglecta* when Devon Island is substituted for the more northern Ellesmere (where this species is not known to occur). Like *Calamagrostis neglecta*, two more of the five remaining 'marsh or heath' plants, namely, *Rubus Chamæmorus* and *Tofieldia palustris*, reach north of 75° only as depauperated relics eking out a precarious existence in one or two localities in West Spitsbergen where the climate is much tempered by the Gulf Stream, while the remaining three also are characteristically more southern plants which merely straggle northwards in a few favourable healthy areas.

It may accordingly be said that truly arctic vascular plants are usually perennial dwarfs which can propagate vegetatively or flower and ripen seed in the short cool summer obtaining north of 75°, and can endure cold and rapid changes in water-relationships, but are unable to withstand competition. They flourish in the Far North where the communities are generally open; to the south they rather naturally persist chiefly where conditions prevent the growth of ranker dominants. and where the growing season is not too long and warm for their normal metabolism. Thus in the British Isles the majority are rare alpines of rock crevices or other 'open' habitats. It is without doubt only the persistence of such habitats in Britain which has allowed the survival (or perhaps in some cases recent introduction) of so considerable an arctic element in the British flora.

---

[2] Names and other details of the individual species and varieties concerned will be published in the *Journal of Botany*, 77 (September 1939).

WILLIAM SMITH (1769-1839), THE FATHER OF ENGLISH GEOLOGY

On August 28, 1839, 'Strata' Smith, as he was familiarly known, died at the house of a friend in Northampton. He was on his way to a meeting of the British Association in Birmingham, to which he had been specially invited, but was taken ill before he could continue his journey. Thus passed away, at the age of seventy years, one of the greatest figures in British geology.

Smith's contributions to science are too well known to need more than brief mention here. After establishing that the different rock strata encountered in the course of his work as a land surveyor always occurred superposed in a particular order, he also discovered that individual strata could be recognized by the fossils they contained. He tested these fundamental observations in various parts of England and everywhere found support for his theory. His conclusions, and the extensive observations on which they were based laid the foundations on which the whole structure of British stratigraphy is built. Further, as has been pointed out by Bather, the recognition of a regular succession of strata introduced the idea of relative time, and without this premiss, no proof of evolution is possible. Thus, it can fairly be claimed that Smith had an indirect though very important influence on the birth and development of the theory of evolution.

At an early date Smith formed the habit of recording his stratigraphical observations accurately on topographical maps. He evolved the idea of showing, by different colours, not only the area distribution of the various strata, but also their structural relationship, that is, the vertical order in which they occur. Some of his early maps were exhibited to various societies, but the first to be published was his famous "Delineation of the Strata of England and Wales, with part of Scotland" (1815). This is a large-scale detailed map embodying the results of Smith's labours over a period of some twenty years, and is the first published geological map of England and Wales. Smith was thus one of the pioneers, if not the actual founder, of geological cartography in Britain.

In order to understand how Smith came to make his discoveries, and to appreciate their influence on contemporary thought, some knowledge of his early life is necessary. He came of farming stock, and, in 1787, at the age of eighteen years, he became assistant to a surveyor at Stow-on-the-Wold, in Gloucestershire. Four years later, in 1791, he was entrusted with the survey of an estate in Somerset. Smith records that this was the year in which his first observations on stratigraphy were made, as a result of having been particularly impressed by the regular stratification of the Lias in the latter county. He continued to work in Somerset for some years, and during this period took the opportunity of acquainting himself with the principles of canal construction, a branch of engineering then much to the fore.

Afterwards he obtained an appointment as engineer to the projected Somerset Coal Canal, and Phillips, his nephew and biographer, says "it was the necessity of a close and accurate knowledge of the different sorts of rock, sand, and clay, which were to be cut through on the line of the canal, which led him to examine minutely and scrupulously into the distribution of the 'extraneous fossils' which he had been in the habit of collecting". Work on the canal commenced in 1794, and by 1799, at the latest, Smith was convinced that different strata in the neighbourhood of Bath could be identified by their fossils.

At this time geology had only just begun to establish itself as a separate science, and Smith's discovery was entirely novel, at all events in Great Britain. Yet he was able to support his conclusions with such strong evidence that he had no difficulty in converting to his views two enthusiastic and well-informed local geologists, the Rev. Benjamin Richardson and the Rev. Joseph Townsend. These gentlemen at once realized the importance of his discovery, and induced him to draw up a table of the strata around Bath, from the Coal Measures to the Chalk. This historically important document was copied and widely circulated both in Great Britain and abroad, but, unfortunately, it was not immediately published. As there was no formal publication of Smith's discoveries until a number of years later, his claim to be regarded as their author passed unrecognized except by his intimate friends, and it was long before he received the honours that were his due.

Meantime, Cuvier and Brogniart had begun to study the Tertiary deposits of the Paris Basin, and they arrived at the same conclusions as those which Smith had deduced from an examination of the English Jurassic rocks. Their results were published in 1808, and it is interesting that the same principles should have been discovered independently at approximately the same time in England and France. There is no doubt of Smith's priority, and it is clear that he achieved his results uninfluenced by the ideas of other workers. Whether the circulation of his views had had any influence on the Continent is not known.

Although Smith's claim to fame rests on his pioneer discoveries in geology, it should not be overlooked that he achieved distinction in his profession as surveyor and engineer. For many years his services were much in demand in an advisory capacity for problems of land drainage, schemes for protection from the inroads of the sea, water supply, and canal engineering. In fact, his first publication (1806) was an account of the draining of Brisley Bog, for which achievement he had received a medal from the Society of Arts. His application of geological principles to these problems undoubtedly contributed largely to his professional success. He was always alive to the economic possibilities of his knowledge of geology and his discoveries had an important bearing on, for example, the development of the British coal fields.

Rather surprisingly, Smith never became a member of the Geological Society of London, although he was resident in London for some years after its formation in 1807; and this Society was somewhat slow in affording him adequate recognition. In later life, however, it made him the first recipient of the Wollaston Medal. The announcement of this honour was made in Smith's presence at the first meeting of the British Association, held in York in 1831. He received the medal in 1832 from the hands of Sedgwick, who, in a laudatory address, referred to him as the "Father of English Geology". In 1835 Trinity College, Dublin, conferred on Smith an honorary LL.D.

It is satisfactory to be able to record that suitable honours were accorded to Smith during his lifetime. Later a monument to his memory was erected at Churchill, Oxfordshire, his birthplace; and memorial tablets have been placed on a house occupied by him at Midford, near Bath, and in Bath itself, on the former residence of the Rev. Joseph Townsend, in which he dictated his famous table of the strata near Bath.

V. A. E.

PHOTOGRAPHY IN SCIENTIFIC RESEARCH

A conference was held in Manchester during July 3–4, under the auspices of the Manchester and District Branch of the Institute of Physics, and under the chairmanship of Dr. F. C. Toy, and was devoted solely to photography, with the principal object of giving an opportunity for discussion of the many photographic problems met with in scientific research, where photography plays so large a part. A large amount of time was necessarily given to reviews on the various aspects of photography and its applications, but in the first session fundamental problems of latent image formation were discussed and some original work was reported; this will occupy most of the space available for the present report.

Prof. N. F. Mott opened the session by a "Description of the Photographic Processes in Terms of Atomic Physics", Dr. J. L. M. Brentano, Dr. W. F. Berg and others contributing to the discussion. Dr. S. O. Rawling gave a paper on "Some Theories of the Action of Developers". Much of the matter dealt with has already been reported in NATURE[1] and elsewhere. The latent image which can so far be revealed only by the process of development was assumed to be a small speck of silver. Modern atomic theory enables a more detailed model of the flocking together of the isolated silver atoms formed by light to be given[2]. The silver halides are photo-conductors, that is, mobile electrons are formed if light is absorbed.[2] The silver halides are also electrolytic conductors: some silver ions (in 'interstitial' positions) will move through the crystal if an electric field is applied. Thus, if there is a place in the crystal where electrons can be collected and held 'trapped', a field will be set up and the ions will move up and neutralize the electrons, thus forming metallic silver. A piece of silver in contact with silver halide constitutes such an electron trap. In this way, once a small speck of silver is formed it will continue to grow if light is absorbed by the crystal. During that process the halogen atoms must escape, otherwise a regression would occur. It is important that in the model suggested the halogen will escape through the crystal surface and will not be liberated at the interface of silver and silver halide. The depth of the electron traps can be determined optically by the Herschel effect: red light will release electrons from the traps and thus bleach the latent image. Thermal energy would not be enough to release electrons, and thus a silver speck in contact with silver halide is stable.

The migration of atoms through solid bodies by a process in which electrons and ions move separately, is a fairly general phenomenon. It occurs, for example, in the atmospheric oxidation of metals, as is shown by the dependence of the rate of that process upon the oxygen pressure[3]. A similar mechanism is responsible for the thermal disintegration of certain azide compounds at 100° C.[4].

To understand the formation of the photographic latent image itself it is necessary to assume the existence of an electron trap before exposure. This probably consists of impurities like silver sulphide, the so-called sensitivity specks[5]. A very small silver speck is considered to be not as stable as a larger one; electrons and ions may 'evaporate' from, and thus break up, a small speck[6]. This process was regarded as responsible for the 'reciprocity failure' at low intensities; at constant exposure (intensity × time) the density depends on the intensity level, because at low intensities a speck may partly evaporate, and thus be too small to make the grain developable, whereas at higher intensity the speck reaches a stable size more quickly without losing matter by evaporation.

Some of the experiments reported by Dr. Brentano appeared to require at least some qualification of this picture. These experiments were made on diluted emulsions, thus avoiding the complications due to the multi-layer nature of commercial materials. The shape of the foot of experimental characteristic curves required the assumption that a grain must absorb 10 or more quanta to be made developable. This is of importance for the consideration of low intensity reciprocity failure and suggested experiments in which a certain exposure was given in a few instalments, with varying intervals of time in between. Below and near the threshold, exposures were additive, even when separated by intervals up to 300 hours. Thus, a markedly stable result is obtained already at the very first stages of an exposure. At higher densities, an interruption of an exposure causes a regression, which is greatest where the characteristic curve is steepest. For small exposures an interruption after ⅓, ½ or ⅔ of the exposure has been given causes the same amount of regression. Several breaks even when close together cause a larger regression than a single break. These findings might be accounted for in two ways. One is to assume that the last electron or ion joining a growing speck is for some time in a less consolidated state. The other is to modify the assumption of the small specks breaking up and getting lost by a hypothesis introducing a certain delay in the early stages of latent image formation.

Two groups of experiments were made with the intention of showing whether such a delay could be due to a process of temporary trapping of electrons outside the latent image. Experiments in which exposures to light of different wavelength, balanced to produce the same density for the same time of exposure, were added, showed a small but distinct difference in density if the order of the exposures was reversed; this was interpreted as demonstrating a small amount of trapping[8]. An X-ray examination of the state of crystalline perfection of a number of emulsions showed that in general the more sensitive emulsion grains are subdivided into smaller crystallites as indicated by the broadening of the X-ray lines. Another possible interpretation is the existence of a bigger strain in the more sensitive grains. As a particular instance it was mentioned that sensitizing by mercury vapour produced such a broadening. This may be cause or part-effect of the increase in sensitivity.

Reciprocity failure has been shown to be, at least to some extent, a development effect, the rate of development depending on the intensity of the exposure[9]. This effect has not been explained satisfactorily, requiring a deeper insight into the mechanism of development.

The process of development may be explained by a mechanism similar to that of latent image formation, the developer being regarded as a medium that will hand over electrons to the latent image. Thus, a field will be set up, and interstitial silver ions will move through the silver halide. For this process to work, the developer must come into intimate contact with the silver speck. The difference in adsorption between various agents, which might otherwise be suitable as developers, may be regarded as responsible for the differences in their behaviour. Another point of view considers the reduction of the silver to occur in the solution, which soon becomes supersaturated and deposits silver on to the latent image. Since the solubility of silver halides in ordinary developers is low, this is probably not the most common process. According to still another view, the silver speck is only incidental to latent image formation, which is considered as being the removal of some of the surface charge of the grains. This charge ordinarily inhibits contact between the developer and the grain, but when it is removed, contact becomes possible.

The Gurney-Mott theory[4] has given rise to a series of papers undertaken to test that theory. Application of low temperature seemed the obvious means of doing this, since ionic movement is then slowed down or arrested. The experiments lead to the following views[9]. At low temperatures free electrons are formed and then trapped, partly in the sensitivity specks, partly in other less stable trapping centres in the grain. The depth of the traps could be investigated by releasing the trapped electrons by red and infra-red light. Ionic movements occur on warming up only and depend solely on the total number of electrons trapped, which in turn depends only on the total number of quanta absorbed. Thus, no reciprocity failure should occur at these temperatures, as has actually been shown[10,11]. These experiments, while compatible with the Gurney-Mott theory, cannot be regarded as proving it, since several additional hypotheses were required for their explanation. The value of the theory as a working hypothesis that had given new stimulus to research into photographic problems was stressed.

Mr. E. R. Davies's paper on "Some Important Properties of Photographic Materials" in which the basis for many applications of photographic methods in scientific research were given, and the advantages and dangers of these methods pointed out, was given in his absence by Dr. Berg[12]. Mr. C. W. Bradley, Dr. J. G. Wilson, Dr. C. A. Adams, Dr. C. A. Bruck and Prof. W. H. Lang then gave examples of the application of photographic methods to specific problems. The three principal advantages of the photographic method lie in the high amplification factor of about 10^{10}: a few quanta striking a grain make the whole grain developable; in the possibility of integrating weak light over long periods—in astronomy the photographic method enables stars to be detected that are ten times weaker than the weakest detectable by the eye; and finally, in the possibility of recording radiation outside the visual range. Some of these advantages have to be paid for; the granular structure leads to loss of resolution due to the graininess and the scattering of light causing 'image spread'. This, however, may sometimes be useful: stellar magnitudes can be determined by the spread of the pin-point images. Many difficulties arise from penetration and exhaustion effects during development, making photographic photometry a difficult problem.

This is further complicated by reciprocity failure, intermittency, and wave-length effects, so that photometry should be based solely on the matching of densities produced by exposures of the same duration and the same degree of intermittency, to light of the same quality and on the same piece of photographic material. Furthermore, the density should be constant over not too small an area. As a beautiful example of this, was mentioned the method of street lighting photography developed in the G.E.C. laboratories[13].

During an evening session, to which a much wider audience had been invited, Dr. D. A. Spencer gave an account of present-day colour photography, illustrated by a cartoon film. This lecture was very much appreciated, and the large attendance showed the widespread interest created. The whole of the conference was very well attended, and the discussion was often very lively, demonstrating the need of informal meetings of this type, in which the aim is partly to bring forward new pieces of research, but partly also to relate already published information of the type not easily accessible to the physicist in industry. The hospitality and general arrangements provided by the Physics Department of the University of Manchester were very much appreciated by al participants.

W. F. BERG.

OBITUARIES

Prof. J. Mellanby

THE death of Prof. John Mellanby on July 15 at the age of sixty years takes from us not only a great physiologist but also a notably genial and kindly personality. He will long be remembered by his colleagues and his students for his penetrating wisdom as well as for his ever-ready willingness to help.

Mellanby went up to Emmanuel College, Cambridge, in 1896 and took Part II of the Science Tripos in 1900, having been an early student under Gowland Hopkins, who had just begun to teach biochemistry at Cambridge at that time. From Cambridge he went to the research laboratory newly founded by Burroughs and Wellcome at Brockwell Hall, and worked there chiefly on the properties of serum proteins and their relation to antitoxins. He left there to complete his clinical course at Manchester and took his M.D. at Cambridge in 1907 and returned to the Cambridge laboratory as George Henry Lewes student. He was still engaged on protein solutions, and in particular on the phenomenon of clotting in blood and milk.

In 1909 Mellanby left Cambridge to take charge of the Physiological Department of St. Thomas's Hospital and began to use the measurement of the clotting-time of milk as a sensitive method for determining the quantity of active trypsin in pancreatic juice, and thus to work out the details of the formation of trypsin from trypsinogen. From the properties of the juice he went on to elucidate the mechanism of its secretion, and it is perhaps his work on this and on the purification of secretin which, together with his earlier investigation of clotting, form his best-known contributions to knowledge.

Mellanby became a fellow of the Royal Society in 1929 and at the time of his death was a member of its Council and of the Medical Research Council. But his purely physiological work was only one part of his activity. What was always in his mind was the encouragement of research from the clinical side, and he was at all times anxious to help, both by advice and in practice, in any problem that might be brought to him. He felt that problems in medicine were problems in physiology and that both were only to be solved by experiment. Such problems arose in the most varied fields and were responsible for example, for his work with Anwyl-Davies on the anti-coagulant action of arsenobenzol and the making of colloidal gold solution, and with C. R. Box on glycosuria.

In 1937 Mellanby became professor of physiology at Oxford and continued there the work on visceral movement to the study of which he had been led by his work on the effects of secretin. He finished an investigation of the changes in size of the spleen shortly before his death. In Oxford, as in London, he was in close touch with his clinical colleagues and his influence on the future of the Nuffield Foundation would have been of immense value. As a researcher he was outstandingly original and versatile, and it is safe to say that time will enhance his reputation in the fields which he made his own.

V. J. WOOLLEY.

Dr. M. A. Usov

THE death occurred on July 26 of one of the most eminent Soviet geologists, Mikhail Antonovich Usov, member of the Academy of Sciences of the U.S.S.R., and director of the All-Union Institute of Co-ordinated Geological Research.

Usov's work was mainly concerned with questions of tectonics and petrology. He elaborated a new method for the study of the tectonics of coal deposits, making use of the vast materials available from underground workings, to which geologists had until then paid little attention. An analysis of the break he had observed induced him to make an exhaustive classification of the forms of volcanic dislocations This resulted in the appearance of several works on the tectonics both of individual mines and of the entire Kuznetsk Basin. In these works he revealed the movement of the Cambrian formations from the direction of the Salair mountain range and the movement of the Devonian formations to the River Tom. These works have become standard guides for mining geologists working in the Kuznetsk Basin. Later, Usov extended his investigations to other parts of the West Siberian Territory. He made a thorough study of the phases and cycles of the tectogenesis of the territory from ancient times to the present day, laid down the principles for distinguishing them and surveyed the tectonic history of the region.

In two of Usov's published works on petrology, "Phases of Effusives" and "Faces and Phases of Intrusives" Usov synthesized the research of the most eminent petrographers, also giving the results of his own research, giving geologists working in the field a method for studying these rocks on the spot.

Usov created a big school of geologists at the Kirov Industrial Institute of Tomsk. He was very interested in the popularization of science, and wrote a number of popular works on geology. He was elected a member of the Academy of Sciences of the U.S.S.R. on January 30, 1939.

NEWS AND VIEWS

National Trust, 1938-39

It is significant of the increased interest of the public in Great Britain's treasures of natural beauty and historic interest—an interest that has grown in proportion as the dangers from building-development have increased—that in the last ten years the properties held by the National Trust or protected under covenant have more than doubled; they now total over 80,000 acres. The gross cost of upkeep, improvements and agents' salaries, according to the Annual Report for 1938–39, exceeds £29,000, while the income from letting, etc., of the properties amounts to £24,650, the difference being met by subscription. The new properties acquired in the period June 1938 to June 1939 number 37 and cover 2,965 acres. Among the more interesting or important acquisitions are 81 acres on Dunstable Downs, 224 acres at Hindhead, Surrey, and more than 900 acres of Dovedale and the Manifold Valley. In addition, 25 properties, covering 7,142 acres, were protected by covenant within the period. Extensive areas are now owned or protected in districts which have been mentioned as prospective national parks. In the Lake District, for example, the Trust now owns 12,000, and protects a further 19,150 acres, while on Exmoor it owns more than 9,000, and protects a further 900 acres. Of Dovedale and the Manifold Valley it owns or protects more than 4,600 acres. At present Cornwall has more coast owned or protected by the Trust than any county; but a considerable stretch of coast in Pembrokeshire will be affected by the recent appeal. The activities of the Trust have been greatly increased by the facilities for cooperation with local authorities under the National Trust Act of 1937, which is now working. Local authorities have already contributed large sums towards preservation schemes in their respective areas. One of the more important undertakings of the Trust, at least from the point of view of the archæologist, is the custody of Stonehenge. Here additional fencing has been carried out and the café demolished; but work on the aerodrome is proceeding only very slowly.

Leadership in Democracy

The seventh Walker Trust Lecture on Leadership entitled "Leadership in Democracy" delivered before the University of St. Andrews by Lord Lloyd on November 14 has been issued in pamphlet form (Oxford University Press. 2*s*.). Lord Lloyd insists that leadership is not the art of becoming and remaining a leader, but the art of leading. It is the opposite of dictatorship, inspiring free men with the feeling of moral obligation to follow. It requires will directed to a high purpose, clearly realized and defined, and courageously pursued. The need for leadership in a democracy, moreover, is even more urgent than in other forms of government because democracy as we know it in Great Britain is a new and untried system of government with no legal restrictions of rights on majority opinion. Lord Lloyd attributes the difficulties and dangers confronting us to-day largely to the absence of leaders who are able to inspire and guide the wills of men to the accomplishment of a high and disinterested purpose. Failure to make up our minds to positive action and to educate and enlighten public opinion has involved incalculable risks. The peril of democracy is its own failure to find the leadership necessary to make its high and necessary ideals triumphant in a world where men are neither naturally wise nor naturally virtuous.

The worst sign of our loss of leadership is the tendency to regard democracy as synonymous with this or that piece of political machinery, regardless of whether the machinery is serving or is capable of serving the aims and ideals for which it was set up. Lord Lloyd urges that in a democracy a leader can only lead if he has the courage to be loyal to faith and conscience and to base all his principles upon them. The first task is to set before the people clearly the ends which they should seek and to show how these ends are shaped and determined by the requirements of Christian morality. Peace at home and abroad can only be based on justice, and if we are to play our part in the preservation of liberty here and its restoration abroad it can only be by promoting a clear understanding of the ends to be pursued and of the kind of society necessary for human well-being. Justice and freedom must first be established before peace can be secured. A peaceful civilization can only be built on a foundation of free men; men subject to misgovernment are no more free men than men subject to a tyranny. We are in danger of losing our great heritage of freedom by surrendering to political expediency, and lack of courage and candour have brought us to the edge of catastrophe.

Damage by Rabbits

THE economic loss to farmers and others through damage caused by rabbits reaches a large annual sum, and it has long been a grievance that much of the damage was done by rabbits bred on adjoining property, over which the sufferer had no control. The "Prevention of Damage by Rabbits Act", passed through Parliament in July, helps to right this state of affairs. It empowers county councils to serve a notice requiring an occupier of land either to destroy his rabbits or to fence them in, and the penalty for non-compliance with such a notice is £25 together with £5 per diem for a continuing offence. County councils are also empowered to provide men and equipment for assisting occupiers to keep down their rabbits, and cyanide fumigation and similar methods of rabbit-control are legalized. The Act also imposes a heavy penalty (£20 for a first offence) for using or permitting the use of spring traps for rabbits elsewhere than in rabbit holes, that is to say, "under the roof" of a rabbit hole. The Bill was promoted at the instigation of the Universities Federation for Animal Welfare, and the secretary of the Federation is prepared to send "Instructions for Dealing with Rabbits" to any person interested who may apply to him at Gordon House, 29 Gordon Square, London, W.C.1.

Ancient Greek Measures and Athletic Records

A REVISED estimate of Greek units of linear measurement would appear to emerge from a study of the records of feats accomplished in the long jump by athletes of ancient Greece in the great festival games. M. Evangelos Kalfarentzos, Inspector-General of Physical Education at Athens, in a communication presented at the conference in connexion with the Lingiad Gymnastic Festival (*The Times*, July 31) arrives at the conclusion that the length of the remarkable jumps attributed to certain famous performers must be computed in terms of a 'foot' which was not uniform in all parts of the Greek world. He bases his argument on the evidence of a comparison of the reputed size of the stadium with the measurements of the various stadia as shown in the results of modern excavations. While it is true that the stadium at Olympia measured 600 'feet', it is an error, M. Kalfarentzos maintains, to hold that all stadia were of this length. Thus the stadium at Delphi was 1,000 'feet'. The actual length of the Delphi stadium was 177·55 metres which, divided by 1,000, gives a 'foot' of 17·76 centimetres. Phaullus, the winner at the Pythian games, as he is named by contemporary writers, is universally accredited with a 'record' jump of 55 'feet' and he is said to have been the first to clear the ditch of soft earth of 30 ft. breadth. Calculated on the revised estimate of the Delphic foot, this jump measures 9·77 metres, or almost exactly 32 feet according to British measurement; while the jump of Chionis, winner at the Olympic games in 664 B.C., is computed at 7·05 metres, or 23 ft. 1 in., on the basis of a 'foot' of which a nominal 600 went to a stadium length, which has been shown to be 192·25 metres.

Further Discoveries in Mycenean Greece

EXCAVATORS on Mycenean sites in Greece during the past season have indeed been fortunate. No fewer than three discoveries of major importance have been made—the inscribed tablets from the "Palace of Nestor", the first from a Mycenean site, which, though later, may throw light on Cretan script, the Mycenean Royal tomb at Athens, and now a Mycenean royal burial, probably of a queen, which has been found by the Swedish Archæological Expedition under Prof. Axel W. Persson of the University of Uppsala at Dendra in the Peloponnese (*Illustrated London News*, August 19). The expedition, which had set out with the intention of excavating at Mylassa in south-west Asia Minor, but was prevented by the political situation, attacked as its second string, the site of Midea, near Nauplia, with which the director was already acquainted, and where he had opened a royal tomb in 1926, finding the gold 'octopus' cup. Midea, according to Thucydides, was a vassal state of the Mycenean rulers.

THE expedition first located the royal palace, and then opened five tombs, one of which, relatively small, contained a beautiful collection of late Mycenean pottery. Three of the tombs were of exceptional size and all had much to offer of interest to archæologists. Three had been more or less stripped by grave robbers; but one of them from an unplundered pit yielded a fine collection of bronzes, knives, swords and cups, while in another were the first known wooden coffin and bronze helmet of Mycenean date. The fourth grave, however, in which the entrance, approached by a dromos of considerable dimensions, had not been touched since it was sealed, contained a wealth of gold and silver objects of great artistic merit, with which no finds in Mycenean Greece since the days of Schliemann will bear comparison. In the smaller of two pits, which contained the badly preserved remains of a skeleton, were golden necklaces, a large gold cup weighing 100 gr., a signet ring of gold, and a number of gold rosettes, rings and pendants. More than two hundred gold ornaments belonged to five necklaces of different types, and there were more than 1,000 pearls of glass paste, and about one hundred of Baltic amber, the first to be known as of Mycenean date. The second pit contained burial gifts, including terracotta and silver vases, and the first known Mycenean spoon. The pottery suggests a preliminary dating of 1400 B.C.

Cornish Promontory Forts

INTEREST in the promontory forts of Cornwall has been much stimulated by the results of Dr. Mortimer Wheeler's excavations in Brittany. One of them, the large and evidently important fort of Trevelgue Head and Porth Island, Newquay, has been under excavation since July 3. Its investigation is being carried on under the direction of Mr. C. K. Croft Andrew on behalf of the Cornwall Excavations Committee. Excavation is still in progress, though much hampered through lack of funds; but the finds reported to date (*The Times*, Aug. 15), ranging from Neolithic to Early Iron Age, fully bear out anticipation of the importance of the site, based partly on its superficial resemblance to Hengistbury Head, Hampshire, partly on the imposing character of its septuple line of defences. The main defences are now assigned to the third century B.C., when there supervened an occupation rich in artistic and metallurgical attainments. The pottery is akin to that of Glastonbury Lake Village, displaying curvilinear and lenticular decoration, as well as naturalistic leaf and vegetable forms. It would appear that in order that the outermost defences should include a native iron mine, they were given an eccentric form. At the back of the sixth, the innermost, rampart was banked the refuse of a considerable Iron Age town. This consisted of houses, or large huts, arranged terrace-wise on the slope rising from the back of the sixth bank to the apex of the island. The best example of a house cleared as yet was occupied from about 200 B.C. to A.D. 100. It is nearly circular and 46 ft. across, the upper sector being sunk two feet deep in the soft slate rock. It shows some fine examples of dry-walling. The wall was probably never more than 4 ft. or 5 ft. high, but it was 6 ft. thick. The roof ran up from eaves which were supported on a ring of external posts, while the span, being too great for early carpenters, was supported by rings of inner posts.

Radio for Short Distances

THE use of ultra-short waves in radio transmission for keeping police cars in touch with headquarters has proved itself of great value. A.R.P. necessities are increasing the demand for this system of communication. There are also a number of uses to which it can be usefully employed in connexion with switching on and off street lamps, water heaters during peak loads, calling air raid wardens and firemen and there would still be space in the high-frequency band for further applications, which are sure to be suggested within the next few years. Had the cost of these installations not been so high the progress made would probably have been more rapid. Sudden changes in the temperature will also encourage the installation of load-controlling equipment. One of its most useful applications is in connexion with fire-fighting. Experience gained in a recent local blackout shows that ordinary telephone communications can break down under the stress of a sudden emergency. The *Electrician* of August 18 says the Post Office has allotted a limited range of frequencies in the ultra-short wave band for police and fire-brigade purposes and that experimental work is being carried out by the Post Office in association with the Home Office to ascertain the possibility of developing local systems of this type. In dealing with emergencies, speed of communication is of the highest importance and wherever it is feasible to provide an effective means by which police, fire-brigade and ambulance headquarters can keep constantly in touch with their mobile units, this should be done.

Broadcasting over the Power Mains

DEMONSTRATIONS have recently been made of the broadcasting of messages over the electric light and power mains. In 1927 the method was conceived by Captain P. P. Eckersley, who, at that time, thought that the B.B.C. should deal with this special transmission. There is no technical defect in the method. For example, a message can be sent from any sub-station to all the consumers with which it is connected. The messages traverse one of the underground mains and get back to earth by a leakage circuit which contains the signalling device. This system has the advantage that it can be applied very readily. It needs no overhead wiring and so is less vulnerable to attack during a war. It could reach the nine million people in Great Britain who are supplied by a company with electric lighting in their homes. If domestic telephones were used, only two million homes would be available. The following objection to the method has been urged by some engineers. It is said that in time of war or civil commotion, enemy agents could easily inject messages into a power mains system and that it would be difficult to locate where they were working until the mischief had been done. Similarly, they might be able to jam any official message to the public. Seeing that power networks are sectionalized it is improbable that pirate messages would reach more than two or three hundred people at most. If a telephone service were used the number of listeners affected would be about the same as with the power mains system. In either case it would not be difficult to devise a method of locating and cutting off the offender. Electric supply engineers are quite enthusiastic about the broadcasting method. Captain Eckersley and Mr. W. B. Woodhouse are urging that a conference of all bodies interested should be called in order to decide, without further delay, what is best to be done.

Vocational Training for Firemen

A BULLETIN, "Vocational Training for Firemen" (Vocational Division Bulletin, No. 199, Trade and Industrial Series, No. 57. G.P.O., Washington, D.C. 10 cents) issued by the Office of Education, U.S. Department of the Interior, gives a general account of the present status of firemen training in the United States, particularly with reference to programmes developed in co-operation with public vocational education. The estimated loss by fire in the United States in 1937 was 285 million dollars, and the growing demands upon the fire service have increased the importance of training all members of fire departments sufficiently to enable them to utilize the results of technical progress and to apply scientific knowledge in fire-fighting and prevention. Since 1930, the International Association of Fire Chiefs has been responsible for a programme of training and development, and in 1937 fireman training schools were organized in connexion with State programmes of vocational education in twenty-two States, in which 5,441 firemen were enrolled. The training programmes include a system of zone or regional schools for training within a wide area; extension classes, chiefly in connexion with a State college or university; short courses or institutes providing three to five days of instruction annually; and local training programmes in the larger cities. Vocational training agencies appear to be of assistance chiefly in the training of instructors or conference leaders; the organization of instructors' conferences; the supervision of training programmes, particularly in the zone schools; the provision of instruction in practical and technical subjects through extension classes or short courses and the supply of literature for instruction and teaching. The bulletin also discusses the methods of assisting a local fire department in organizing a training programme and the possibilities of co-operation with other agencies. Details of the organization and administration of the Massachusetts zone schools are appended and also of the California programme.

Hygiene and Public Health in India

THE annual report of the All-India Institute of Hygiene and Public Health, Calcutta, recently issued, summarizes the teaching and research work for the year 1937. Statistical investigations on cholera have been pursued; for example, forecasts of epidemics, and research on variations in the chemical structure and antigenic properties of the cholera vibrio. An inquiry into the nature of an obscure disease, epidemic dropsy, has incriminated mustard oil (much used in cooking) as the causative agent, though what constituent of it is responsible still remains to be discovered. An account of the work of the Maternity and Child Welfare Centre is included.

Tuberculosis in Cyprus

THE National Association for the Prevention of Tuberculosis has published an interim report on the incidence and means of control of tuberculosis in Cyprus ("Tuberculosis in Cyprus", by N. D. Bardswell. M. D. Adlard and Son, Ltd., 21 Hart Street, W.C.1. 2*s*. 6*d*.). Tuberculosis was said to be rife in the island and to be increasing rapidly; the assistance of the National Association was requested, and Dr. Bardswell was appointed to conduct an inquiry in the island. A total of 250–300 notifications of pulmonary tuberculosis a year is recorded in a population of some 360,000. If a correct record, this would give a notification rate for pulmonary tuberculosis of less than 1·0 per 1,000 living—not a high rate, for the present rate (1935) for England and Wales is 0·97, and for London 1·27, per 1,000 living. There is reason to think, however, that the notification returns are inaccurate, and do not represent more than onequarter to one-half of the new cases occurring annually, owing to failures to notify all cases and to inaccuracies in diagnosis. Dr. Bardswell has surveyed the whole island, and the results of tuberculin testing in some districts are given. The report contains a mass of details, and is well illustrated with maps, plans, charts and photographs. It is difficult, however, to gather the actual facts and conclusions from this report of 228 pages, for it contains no table of contents, no index, and no general summary; these omissions should be made good in any further report.

Scientific Uses of Cinematography

THE British Film Institute, 4 Great Russell Street, London, W.C.1, one of the objects of which is to collect and disseminate information concerning the use of films for educational purposes, is engaged in compiling a bibliography on the scientific uses of cinematography. Very few books have been written on the subject and the list will consist almost entirely of references to reports of scientific associations and to articles which have appeared in scientific and film journals. The Institute would be glad to receive any information bearing on the undertaking.

Water Speed Record

SIR MALCOLM CAMPBELL set up a new record for speed on water on August 19 with his motor-boat *Bluebird II* on Coniston Water. The speeds reached over a statute mile in opposite directions were 142·85 and 140·62 miles an hour respectively, the average being returned as 141·74 miles an hour. Sir Malcolm's boat, in the design of which some novel features were embodied, was driven by a twelve-year-old engine intended for practice runs.

Recent Sunspot Activity

THE appearance this week of a large group of sunspots serves as a reminder that the sun is still very active though past the peak of the present 11-year sunspot cycle. This sunspot group, in latitude 13° N., crossed the central meridian on August 21·9 and will pass off the western edge of the disk on August 28. The aggregate area of the component spots on August 18 was 1,300 millionths of the sun's visible hemisphere. Since the last note on sunspots (NATURE, July 15, p. 109) a number of fair-sized spots have appeared of area greater than 500 millionths but less than 1,000 millionths. The respective times of central meridian passage (communicated by Greenwich) are as follows: July 17·1^d, 17·7^d, 20·1^d, 23·4^d, August 4·3^d, 7·5^d and 11·1^d U.T.

The Night Sky in September

THE autumnal equinox on September 23 brings equality of day and night the world over; thereafter (until December 22) the nights increase their duration in the northern hemisphere. The moon is new on September 13 and full (the Harvest Moon) on September 28. Jupiter is in conjunction with the moon on September 1 and 28: Saturn on September 3 and

SHORT REVIEWS

Anthropology

Singing for Power

The Song Magic of the Papago Indians of Southern Arizona. By Ruth Murray Underhill. Pp. vii+159. (Berkeley, Cal.: University of California Press; London: Cambridge University Press, 1938.) 9*s*. net.

MISS UNDERHILL here collects some of the songs which are a characteristic feature in the life of the Papago Indians of southern Arizona. The collection is part of a more elaborate study of Papago ceremonial, for which the material was collected in two expeditions undertaken under the ægis of the Humanistic Council of Columbia University, and occupying fourteen months in 1931 and 1933.

The songs are an essential part of the ceremonial ritual which is concerned with every department of daily tribal life, of rain-making, and in the preparation and first drinking of cactus spirit, 'singing up' the corn, war and scalping ceremonial, puberty and the like. It is interesting to note that the man who has taken a scalp, thereby acquiring magical power, is a danger to others. He has to learn a code of behaviour, whereby he may avoid harmful direction of his powers against fellow members of his group.

In addition to a translation, each group of songs has explanatory notes making clear its position and function in life and belief.

The Native Tribes of Central Australia

By Prof. Sir Baldwin Spencer and F. J. Gillen. New edition. Pp. xxiv+671+9 plates. (London: Macmillan and Co., Ltd., 1938.) 25*s*. net.

A REPRINT of "The Native Tribes of Central Australia" by the late Sir Baldwin Spencer and F. J. Gillen is more than welcome. The original edition appeared in 1899 and has long been out of print. It is now reproduced without change, but with an introduction by Sir James Frazer, to whose inspiration, counsel and friendship Spencer's work as an anthropologist was so deeply indebted.

"The Native Tribes of Central Australia" may without exaggeration be described as the most important ethnographical treatise on a primitive people ever written. Dealing mainly with the Arunta, it included material relating to other tribes of Central Australia, which Spencer did not incorporate in his later books.

Among the author's discoveries, the record of the classificatory system of relationship current among the Arunta, which effectually prevented intermarriage within the 'forbidden degrees', fully confirmed the earlier work of Fison and Howitt in other parts of Australia; but the outstanding achievement of the investigators lay in eliciting that the Arunta were ignorant of the facts of paternity and of the nature of the process of procreation, and in establishing that the totemic ritual was a magical ceremonial for the increase of the totem—plant or animal. Hereby Spencer and Gillen opened up new vistas in the exploration of the primitive mind in its social and religious orientation, and initiated a new conception of the totemic problem, which for so long had exercised the ingenuity of the anthropologist in speculation.

"The Native Tribes of Central Australia" indeed proved to be in a very real sense an epoch-making book.

Biology

Salmacis (The Indian Sea-Urchin)

(Indian Zoological Memoirs on Indian Animal Types, edited by Dr. K. N. Bahl, 7). By Prof. R. Gopala Aiyar. Pp. ix+69+1 plate. (Lucknow: Lucknow Publishing House, 1938.) 2 rupees.

THIS memoir gives an account of a common Indian sea-urchin which is a fairly typical example of the class Echinoidea. The introductory chapter deals with systematics and so with the position of the genus Salmacis among the Echinoderms. The definitions of the various orders of the Echinoidea are given, and with each order a list of the commoner Indian forms. The example belongs to the family Temnopleuridæ, and a key is provided for the separation of the genera of this family. The next nine chapters provide a systematic account of Salmacis under a succession of headings; external characters, skeleton, alimentary canal, cœlom, connective tissues, respiratory and excretory organs, nervous system, receptor organs and reproductive system. The next three chapters treat of the development of the Echinoidea (some of it based on the classical account by Prof.

E. W. MacBride in the "Cambridge Natural History"), the bionomics and directions for practical work.

Thus it will be seen that the book provides a complete manual for the use of the student of zoology. Its exact utility must be tested by experience, but it certainly appears to be full of promise. It is now twelve years since the appearance of the first of the Indian Zoological Memoirs, and this is the seventh to appear. All of them have exhibited a high degree of technical excellence. The present memoir does not fall below this high level, and the only criticism from this aspect is that, in the example submitted for review, the photograph of breeding Salmacis is not well reproduced; it is not up to the standard of the remainder of the illustrations. Zoologists in India owe a debt of gratitude to Prof. Bahl, to whose enthusiasm this series of memoirs is due.

Further thanks and congratulations are due to Prof. R. Gopala Aiyar for the excellent and workmanlike account of this Indian sea-urchin.

The Birds of Tropical West Africa

With Special Reference to those of the Gambia, Sierra Leone, the Gold Coast and Nigeria. By Dr. David Armitage Bannerman. (Published under the authority of the Secretary of State for the Colonies.) Vol. 5. Pp. xliii + 485 + 10 plates. (London: Crown Agents for the Colonies, 1939.) 22*s.* 6*d.*

FACTS mentioned in the preface to Dr. Bannerman's fifth volume bear witness to the success which the work has already attained. It is indeed remarkable evidence of widespread interest in ornithology that so ambitious a publication, dealing with the avifauna of a tropical area, should have sold beyond anticipation—to such an extent that the first volume is almost out of print. The stimulus given to the study of birds in West Africa, and in the African continent generally, must have been great; this is confirmed by the increasing amount of new material which has been reaching the author and has made it necessary to provide for a seventh volume not originally planned.

The present volume covers seven passerine families, of which the warblers account for 121 forms. The admirable coloured plates portray sixty-seven species, in addition to the many illustrations which accompany the text.

Elementi di genetica

Par Giuseppe Montalenti. Pp. vii + 452. (Bologna: L. Cappelli, 1939.) 50 lire.

HERE is an excellent text-book recording the facts relating to every side of genetics; its text is remarkably clear, scientific terms always explained, and its matter is adequately illustrated. A historical consideration of the position in the nineteenth century leads to the full account of Mendel's researches. Then follows the amplification of these. with many new branches, associated with the early years of the present century. The later-discovered chromosome phenomena lead to a clear account of the localization of the genes and the experimental production of mutations. Embryological and physiological sides are sufficiently treated, as are sex secondary sexual characters and other associated sides. A good bibliography, helpfully divided into sections, and adequate indexes of authors and of subjects complete a well-compiled work. Finally, the price of about 11 shillings as compared with about 2 shillings for a similar text-book in English suggests a wide and desirable circulation among those able to read Italian.

The British Caddis Flies (Trichoptera)

A Collector's Handbook. By Martin E. Mosely. Pp xiii + 320 + 4 plates. (London: George Routledge and Sons, Ltd., 1939.) 21*s.* net.

THE need for a handbook on the indigenous Trichoptera or Caddis flies has been long experienced by English entomologists. The present work, to a large extent, supplies this desideratum Its author is well qualified for the task, having been in charge of the collections of these insects in the British Museum for a period of ten years. All the 184 species known from Britain are described, and the letterpress is accompanied by some 633 very clear figures of the venation and genitalia. The descriptions are short and terse and are based on structural features, but little emphasis is laid upon wing-markings.

It is unfortunate that so little is said about the general structure and biology of these insects or about their remarkable larvæ and pupæ, the book being adapted essentially for the identification of the adult insects. Notwithstanding this criticism, a reliable and well-produced volume of this kind can scarcely fail to impart stimulus to the further study of the interesting creatures with which it deals, and English entomologists are under a debt to Mr. Mosely for having written it. The increasing number of workers in the field of fresh-water biology will also find that this book supplies a long-felt need.

Earth's Green Mantle

Plant Science for the General Reader. By Prof Sydney Mangham. Pp. 322 + 41 plates. (London English Universities Press, Ltd., 1939.) 10*s.* 6*d.* net

IT is no doubt a useful and laudable object to explain to the general reader the place in Nature and the importance to man of the plant world. Sir Arthur Hill states in his foreword, "Prof. Mangham has shed such a diffused and widespread light over the Green Mantle of the Earth that the minds of his readers, by a process of mental photosynthesis, should be able to acquire and assimilate vast stores of curious and unexpected information hitherto not fully appreciated." The variety of topics dealt with by the author is, however, so great that one wonders whether the reader will be able to digest this very ample meal.

Prof. Mangham attempts a *tour de force* by ndeavouring to deal with every aspect which plant fe opens out. Not only, for example, does he give n account of the plants of past ages but he also escribes in some detail the rock systems and geo- gical revolutions. It seems doubtful, too, whether he general reader will be able to appreciate fully a istory of botany from Aristotle to the present day nd a fairly detailed account of the structure of lants, recent and fossil.

The book is very fully illustrated, but one feels hat in this respect also the author has been too mbitious. Many of the ecological photographs —excellent in themselves—have lost a good deal of learness by reduction in size. By a more careful election of the illustrations as well as by some utting down of the subject-matter the author's raiseworthy attempt to enlighten the general public n the interest and importance of the plant life would robably be more successful.

oncise Flora of Britain for the use of Schools

Vith Explanatory Illustrations and Keys to Identifica- on. By F. K. Makins. Pp. xxviii+212. (Oxford: larendon Press; London: Oxford University Press, 939.) 4*s*. 6*d*.

N the preface to this book the author states that its object is to meet the demand for a modern lora of Britain suitable for use in schools and by eginners generally, and in describing how to use the lora he claims that its chief use is to enable the udent to identify plants for himself. Short de- riptions of more than 1,100 species are given, in- luding, therefore, the great majority of aggregate pecies of flowering plants and ferns found in Britain. ost of the rarities are excluded. The author has isely refrained from including illustrations which ould give a clue to the identity of any plant, and the ain series of drawings is intended to illustrate the chnical terms given in the glossary. The attention f the young student will very naturally be directed these drawings, and it is a pity that there is no dication of what they represent except by reference the glossary.

The synopsis of families follows fairly closely the rangement adopted in Bentham and Hooker's British Flora", but for the actual identification of milies and anomalous genera an artificial key is rovided which is so constructed that the beginner ould have little difficulty in referring any plant its proper family. Keys to the genera of the larger milies and to the species of the larger genera are ven throughout the book.

The author is to be congratulated on producing very compact form a book which is sure of a wel- me in schools where botany is taught and where udents require an easy guide to the identification the wild plants they are likely to find. The use of e Flora, however, should be supervised by the acher so that the artificial aids to identification ay not lead to a wrong impression of plant affinities.

Chemistry

B.D.H. Reagents for Delicate Analysis including Spot-Tests

Seventh and enlarged edition. Pp. viii+120. (London: The British Drug Houses, Ltd., 1939.) 2*s*. 6*d*. net.

THE fact that a new edition of the popular and useful publication of the British Drug Houses has been called for annually is sufficient proof of the established position which this book has attained. The seventh edition has been carefully compiled to eliminate four reagents which have not stood up to the test of time, and to include four new reagents, for the determination respectively of palladium, magnesium, manganese and aluminium. The scope of the book, which now runs to 120 pages, has been augmented by expansion of the monographs of some of the more important reagents.

The reagents are carefully described, but it is suggested that if it were possible to represent the formula of each reagent graphically as in the case of acridine hydrochloride the value of the book would be enhanced, particularly to those whose interest now lies mainly in inorganic chemistry. Included in the book are separate leaflets, one describing the B.D.H. spot test outfit and the other the B.D.H. price list of the organic reagents described in the book.

This B.D.H. publication has proved of great value as a laboratory guide not only to analytical chemists but also to all research workers whose activities lead them to conduct delicate analysis. By supplying frequent editions of their book, the British Drug Houses keep abreast of the most recent advances in the field of analysis, render their publication the standard work on this topic, and summarize for the practical chemist much valuable but often scattered information. It is sufficient to say that the B.D.H. book should be available in every chemical laboratory.

Theoretical Qualitative Analysis

By Prof. J. H. Reedy. (International Chemical Series.) Pp. ix+451. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 18*s*.

PRACTICAL manuals on qualitative analysis are many, and usually consist of tables of practical directions with little or no explanation of the reactions underlying the processes used. Reedy's "Theoretical Qualitative Analysis" is one of the few books which seeks to give the student commencing a course of analysis a thorough understanding not only of such reactions but also of the general theories which form the basis of analytical chemistry, and indeed of inorganic chemistry as a whole.

General theoretical considerations form the first half of the book and include important chapters on the ionization theory, in which both complete and incomplete dissociation theories are discussed in an unbiased manner. For the most part, however, the author has based his applications on incomplete ionic dissociation, and in this connexion it is noteworthy that ionic equations are freely used in place of the older molecular equations.

Theories explained in the earlier part of the book are used in the second half in giving a full and clear description of reactions forming the classic group system of analysis for cations and anions. Division into chapters follows the group system, and each chapter contains a wealth of classified information, on the elements, cations, anions and compounds dealt with. Used in conjunction with a practical manual, this treatise should train the student to be a more intelligent and therefore a more efficient analyst.

The Structure and Composition of Foods

By Dr. Andrew L. Winton and Dr. Kate-Barber Winton. Vol. 4: Sugar, Sirup, Honey, Tea, Coffee, Cocoa, Spices, Extracts, Yeast, Baking Powder. Pp. xxxiii+580. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 45*s*. net.

THIS volume completes the authors' extensive labours, of which the first, second and third fruits were noticed in NATURE in March 1933, March 1936, and February 1938. The contents are indicated by the title: the method of treatment is congruous with that adopted in the earlier parts. Addenda (pp. xix–xxiii) bring up to date some of the chemical information contained in volumes 1 and 2. To search for printer's errors and other slips would be ungracious and an admission that adequately to appraise a work of this scope and magnitude is beyond the powers of one reviewer at any rate. He has, however, noted that the authors do not appear to have recorded the presence of vitamin D, presumably calciferol, in or on the shell of the cocoa-bean, which has consequently been advocated as a cattle food to increase the antirachitic activity of cows' milk.

The four volumes as they stand now constitute a complete standard work of reference on the subject. Every laboratory concerned with the examination and control of food, with the morphology and chemistry of its natural sources, whether animal or vegetable, with its proximate analysis and detailed chemical composition, will find in "Winton and Winton" an indispensable weapon.

A. L. BACHARACH.

Volumetric Analysis: including the Analysis of Gases

With a Chapter on Simple Gravimetric Determinations. By A. J. Berry. Fifth edition. Pp. vii+196. (Cambridge: At the University Press, 1939.) 7*s*. 6*d*. net.

THE principal part of Berry's well-known work on volumetric analysis remains unchanged in the fifth edition, following the usual division into chapters describing the use of the chief volumetric reagents and including a chapter on the theory of indicators as well as a short section on simple gravimetric analysis. The practical treatment adopted succeeds in its object of going beyond the scope of elementary text-books without entering into the mass of detail to be found in standard analytical reference works.

The chapter on gravimetric analysis contains new sections dealing with the determination of lead and of phosphates; but the most important additions a to be found in the entirely new chapters devoted modern developments and to the rudiments of g analysis. The former includes sections on the mo important new indicators, on the use of ceric sulpha as a quantitative oxidizing agent, and on dire titrations with potassium iodate, together with pra tical applications of these and several other ne methods. In introducing this particular chapter t author has brought his course of analysis complete up to date.

Systematic Qualitative Organic Analysis

By H. Middleton. Pp. viii+279. (London: Edwa Arnold and Co., 1939.) 8*s*. 6*d*. net.

THE title of this excellent book on qualitati organic analysis is fully justified by the co tents, in which a remarkable degree of system h been introduced into the tests for single organic cor pounds. The schemes of analysis and tabulat properties of groups of substances should be of gre value to all chemistry students in the final year an honours course, and it is claimed by the auth that particular attention has been given to pharm ceutical students in that rapid methods are given f identifying most of the organic compounds listed the "British Pharmacopœia". In working throu a course based on this book, the student wou undoubtedly become familiar with all the operatio commonly carried out by the organic chemist, a should acquire a good practical knowledge of ma tests and preparative reactions. A feature valuab to supervisors and examiners is found in a list hydrolysis times of some hundred esters.

Such criticisms as may be made are in a few matte of detail. Thus one cannot agree that acetates, give first of the derivatives of phenols, are the best mediu for the identification of monohydric phenols, t acetates of which are generally liquids. Again, the section on alcohols, melting points of the dinitr benzoates might well have been given under ea alcohol, instead of being referred to under speci reagents.

The book contains a short section on the separati of mixtures of organic compounds and conclud with two indexes—one of the processes and one of t substances described.

A Course in Chemical Spectroscopy

By Dr. H. W. Thompson. Pp. vii+86+8 plat (Oxford: Clarendon Press; London: Oxford U versity Press, 1938.) 6*s*. net.

THIS neat little volume is based on an elementa course in chemical spectroscopy recently intr duced at Oxford for undergraduates reading the fir honour school of chemistry. Eight experimen have been selected, and although no attempt is ma to describe the technical details of construction the various instruments used, sufficient informati is given to enable a student to carry out each expe ment successfully under the general supervision the teacher.

The principal lines in the atomic spectra of the ements are first measured in the visible region, the ilger constant deviation instrument being instanced very suitable. The student then passes on to study ries of lines in the ultra-violet spectra of elements, d a good knowledge of atomic structure is pre- umed. Electronic and rotation spectra come next, hilst the sixth experiment deals with the absorption ectra of gaseous molecules, notably hydrogen dide, chlorine, sulphur dioxide and oxides of itrogen. One would have liked to see also a study the absorption spectra of rare earth salt solutions cluded, in view of the increased attention now ing given to this branch of the subject. Perhaps e author will bear this in mind for future editions, hich we feel sure will be required. The two last periments deal with predissociation spectra and e structure of an infra-red absorption band.

On the whole, the experiments have been well lected. The book is tastefully got up, the type d diagrams are clear, whilst the eight photographs ave been very beautifully reproduced. Any student ho conscientiously completes the course of instruc- on may be regarded as possessing a sound know- dge of the elements of practical chemical spectro- opy.

J. N. F.

he Oxidation States of the Elements and their tentials in Aqueous Solutions

y Prof. Wendell M. Latimer. Pp. xiv+352. (New ork: Prentice-Hall, Inc., 1938.) 3 dollars.

THE contents of Prof. Latimer's book are much broader than might be inferred from the title. esides giving all the available information on oxida- on-reduction potentials in aqueous solutions, care- lly and critically sifted and presented on a uniform lan, it includes a great deal of numerical data based thermodynamic calculations as applied to reactions hich are not directly amenable to electrometric easurement. The volume will be extremely valuable many workers—chemists, physicists and biologists —and it may be cordially recommended to their tention. It is well printed, strongly bound, and ery moderately priced.

troductory Qualitative Analysis

y Prof. Warren C. Vosburgh. Revised edition. Pp. i+222. (New York: The Macmillan Company, 938.) 10s. net.

"INTRODUCTORY Qualitative Analysis", a revised edition of Cornog and Vosburgh's book under e same title, is an elementary laboratory manual imarily intended for students of a particular iversity in the United States. The detailed practical structions, suitable however for general use, include rections for analytical work on a semi-micro scale. ince the author states that qualitative analysis on is modified scale has been carried out at Duke niversity during the past four years, he might well ave taken the bold step of abandoning ordinary ale directions entirely in favour of the new micro ethods.

The theoretical part of the book, providing explanatory matter to be read contemporaneously with the practical exercises, covers the ground adequately and includes general chapters on electrolytic dissociation, chemical equilibrium and the theory of precipitation, in addition to a chapter dealing more particularly with the reactions used in qualitative analysis. It appears a defect that only the theory of complete ionic dissociation is presented, but, in general, the explanatory matter is treated with brevity and clearness.

Engineering

Stream and Channel Flow (Hydraulic Graphs and Tables)

By E. E. Morgan. Pp. xxii+240. (London: Chapman and Hall, Ltd., 1938.) 25s. net.

THIS manual is a convenient compendium of hydraulic graphs and tables for stream and channel flow, calculated from a modification of Manning's formula:

$$v = M\sqrt[3]{R^2}.\sqrt{S},$$

in which v is velocity of flow in feet per second; R, the hydraulic mean depth; and S, the sine of the angle of slope. M is the coefficient of roughness, corresponding to C, the coefficient of roughness in the Chezy formula, $v = C\sqrt{RS}$, which assumes so complex a form in the formula of Ganguillet and Kutter. The reasons for the adoption of the Manning formula, in preference to those of four other prominent authorities, are set out in Chapter xvi. The whole subject of velocity and discharge multipliers is examined at considerable length. The book is devised for ready reference with marginal finger cuts and a central subject indicator. There is also an index.

B. C.

Cement and Concrete

By Rahel Friedland. (Written in Hebrew.) Pp. xii+276. (Haifa: Hebrew Technical Institute, 1939.)

THIS book is claimed to be the first Hebrew textbook in its own field, and will answer a real need in Palestine's rapidly developing building industry. It is written by a member of the staff of the Hebrew Technical Institute, Haifa, presumably as a text-book for its own students. Its style and lay-out are simple and straightforward, and the importance of giving adequate attention to industrial application and practice is fully realized.

Part 1 deals with cement, and is mainly devoted to a consideration of Portland cement; mixed, aluminium, and special cements are dealt with briefly, and the corrosion of cement by acids, alkalis and salts discussed. In each case, the composition, manufacture, physical and chemical properties and methods of testing are adequately described.

Part 2 is concerned with concrete, and chiefly with the composition and properties of concrete, particle size and its relation to the quality of the concrete, the role of water, methods of preparation, the influence of physical factors, specifications for ingredients, and the analysis and testing of concrete.

A summary of Palestinian regulations for building materials and an interesting glossary of Hebrew technical terms are also given.

This book should be found very useful by all interested in the building industry in Palestine, and particularly by those who intend to study this subject in Palestine. It should also be of interest to the philologist, for is it not a miracle that the age-old Hebrew language, used for so long only as a vehicle for prayer and the study of Jewish sacred writings, should to-day be sufficiently revived to enable a scientific text-book to be written in it? N. G.

Industrial Electricity: Direct-Current Practice

By Prof. William H. Timbie. Second edition. Pp. xii+636. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 15*s*. net.

TECHNICAL students and industrial workers who desire to qualify for posts where a knowledge of electrical science is necessary will find this book very helpful as an introduction to the subject. Phrases used in everyday work such as voltage drop, potential gradient, floating batteries, dielectric constant, etc., are not easy to understand without some theoretical basis on which to build. In our opinion, the almost universally used phrase 'dielectric constant' is not very happily chosen as almost all, if not all, of this kind of *constant* varies with temperature. We like this book because it describes the underlying principles of such problems as the stresses in insulators, the action of vacuum tubes, and the phenomena of the karc, the spar and the corona. The object is not to help students to pass written examinations, although it will be a help in this direction as it is well written and thoroughly up to date. In describing electric heating, illustrations are given from electric toasters, stoves, apparatus for air-conditioning, etc.

We were interested to see in this book a photograph of a very up-to-date flat-iron made in America, where electric flat-irons are almost universally used. It was fitted with a device which automatically switched out the circuit when temperature rose to a definite desired value, less than 700° F., which is the highest permissible temperature if scorching is to be avoided. Beyond very elementary algebra, practically no demands are made on the mathematical knowledge of the reader.

Radio Laboratory Handbook

By M. G. Scroggie. Pp. x+384. (London: Iliffe and Sons, Ltd., n.d.) 8*s*. 6*d*. net.

THE methods and measurements used in a modern radio laboratory are described in this work, which includes details and illustrations of the available apparatus for making such measurements. The whole range of alternating current frequencies used in radio and acoustic technique is covered. Practica advice is included on the lay-out and equipment o a laboratory on scientific lines, and some usefu information is provided on the construction and us of many items and components which are auxiliar to the main sets of apparatus. The book should prov very helpful to all those engaged in the use of a radi laboratory, whether from a design and developmen or from a research point of view. R. L. S.-R.

Fundamentals of Radio

By Prof. Frederick Emmons Terman, with th collaboration of Lieut. F. W. Macdonald. Pp. viii-458. (New York and London: McGraw-Hill Boo Co., Inc., 1938.) 21*s*.

THIS book is essentially an abridged version o the author's "Radio Engineering". It present the basic principles of radio communication in form suitable for an introductory course for th physicist or engineer. The treatment is confine very closely to this objective, all reference to th practical applications being reduced to the absolut minimum. The work is, however, quite up to dat in so far as established principles are concerned, an the series of problems at the end of each chapte should be of great assistance to the student using th book. R. L. S.-R.

Geology

Geology and Allied Sciences

A Thesaurus and a Coordination of English an German Specific and General Terms. By Walth Huebner. Part 1: German–English. Pp. xvii+40 (New York: The Veritas Press, Inc.; London Thomas Murby and Co., 1939.) 7.50 dollars.

THE need for a comprehensive German–Englis dictionary of geological terms has long bee apparent to workers in this branch of science, an the work under notice is therefore welcome. Th author has been engaged in its preparation f fifteen years, and certainly the work is not lacking thoroughness. Indeed, so careful has the compil been that no slight shade of meaning should be ove looked, that he may be accused of under-estimatin the intelligence of his readers. It is not difficult find occasional faults in his rendering of Germa terms, and it may be suggested that specialists wou be doing a good service if they accede to the autho request to communicate corrections to him.

The price of the book is perhaps a little high f the average student, and a future edition, it may b suggested, could be shortened without loss b the omission of German terms the English equivalen of which are spelt so similarly as to make the tran lation obvious. Many composite words, too, ha been given though their meaning is so self-explanato as scarcely to call for inclusion in the thesaur Even a reader with the most elementary knowled of both German and geology should be able to dedu for example, through looking up the terms 'basa and 'gang', that 'basaltgang' means 'basalt dike'. In spite of these criticisms, there can be no doubt that this is an extremely useful contribution to geological literature.

The comparative table of the nomenclature of the Lower Palæozoic formations included at the end is incorrect, and, in any event, is unnecessary in a work of this sort.

Mathematics

101 Problems in Drawing-Board Geometry

By Prof. Frederic G. Higbee. Pp. 14+59 plates+26 blank pages. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 8*s*. 6*d*. net.

THERE is no more valuable exercise in clear thinking than the solution of a problem by a graphical method and, by presenting the problem in the form of a partial drawing accompanied by a brief description as Prof. Higbee has done, the value of the exercise is considerably enhanced. After receiving some explanation of the principle to be applied, the student is expected to complete the work in good quality draughtsmanship. He has, therefore, first to visualize the printed data in the few points and lines given, then to formulate a method of applying the principle involved and finally to work out a neat and accurate drawing-board solution. The principles had been demonstrated by the author in an earlier work "Drawing-Board Geometry" and are referred to in the present book, which consists of detachable drawing sheets ready for completion. It offers to the teacher opportunity to develop in his pupils the ability to recognize in the given points and lines the representation by projection of corners and edges of a geometrical figure or of an engineering detail.

Analyse mathématique

A l'usage des candidats au Certificat de mathématiques générales et aux Grandes Ecoles, d'après les Cours professés à l'Ecole centrale des Arts et Manufactures et à la Sorbonne. Par Paul Appell. (Cours de mathématiques générales.) Cinquième édition entièrement refondue par Prof. Georges Valiron. Tome 2: Equations différentielles, développements en séries, nombres complexes, intégrales multiples. Pp. vi+389–694. (Paris: Gauthier-Villars, 1938.) 70 francs.

THIS volume deals with differential equations (ordinary and partial), Taylor's theorem, convergence, Fourier series, complex numbers, double and triple integrals, and the theorems of Green and Stokes. The treatment is much less abstract than in the usual "Cours d'analyse"; worked examples are frequent, and the author uses geometrical arguments whenever they appear simpler than the formal mathematical treatment. There are also references to mechanics and mathematical physics. One of the concluding notes explains the principles of Amsler's and other planimeters, and of the integraph. The style is clear, the printing exceptionally good, and there are many diagrams.

Advanced Mathematics for Engineers

By Prof. H. W. Reddick and Prof. F. H. Miller. Pp. x+473. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 20*s*. net.

AMONG the various text-books which have appeared during recent years and which endeavour to bring advanced mathematical methods within the reach of the engineer this one appears to the reviewer to be of outstanding merit.

The presentation is exceptionally clear and easy to follow, since it indicates always in which direction and for what purpose an argument is being pursued, and the various steps are frequently illustrated by simple well-chosen examples. Not less will the engineering reader value the fact that the authors have shown how these methods work by applying them to a large number of problems covering a wide field of physics and engineering, and that in presenting proofs as well as applications they have considered his limited formal technique.

It is impossible to enumerate all the subjects dealt with. They range from a refresher course in differential equations and infinite series to elliptic gamma and Bessel functions, to the theory of probability, functions of a complex variable and operational calculus.

A. B.

Tables of Addition and Subtraction Logarithms with Six Decimals

By Dr. B. Cohn. Second edition. Pp. viii+68. (London: Scientific Computing Service, Ltd., 1939.) 10*s*.

IF we are given the logarithms of two numbers, to find the logarithm of their sum by the aid of ordinary logarithmic tables, we must use the tables three times and perform one addition. If, however, a table of addition logarithms is available, we have only to use them once and perform one addition and one subtraction. Similarly, we use subtraction logarithms to find the logarithm of a difference. The saving of time is appreciable in spherical trigonometry, as used in navigation and astronomy. Dr. Cohn's tables are clearly printed, and include brief instructions for their use, with numerical examples.

The Nomogram

The Theory and Practical Construction of Computation Charts. By H. J. Allcock and J. Reginald Jones. Second edition. Pp. viii+224. (London: Sir Isaac Pitman and Sons, Ltd., 1938.) 10*s*. 6*d*. net.

THE nomogram is very convenient for representing the values of a function of two or more variables. In its simplest form it consists of three lines (possibly curved), two graduated to represent the values of the variables, and the third to represent those of the function. To use it we have only to place a ruler through the two points representing the variables, and its intersection with the third curve will give the corresponding value of the function. The new edition includes circular and set-square-index nomograms. For the theory, the authors rely upon determinants and Cartesian co-ordinates.

Introduction to the Theory of Equations

By Prof. Louis Weisner. Pp. ix+188. (New York: The Macmillan Company, 1938.) 10*s.* net.

THE distinctive feature of this book is the emphasis on the concept of a field. This serves as a unifying principle connecting the various parts of an elementary course in the theory of equations, including complex numbers, the theorems of Sturm, Budan, and Descartes, elimination, symmetric functions, cubic and quartic equations, but excluding determinants, which are assumed to be known. The fundamental theorem of algebra is treated, rather unusually, by Gordan's method, reducing the theorem to a property of continuous functions which is stated without proof. The final chapter deals with ruler and compass constructions. There are many examples.

Gewöhnliche Differentialgleichungen

Von Prof. Dr. Guido Hoheisel. (Sammlung Göschen, Band 920.) Dritte neubearbeitete Auflage. Pp. 126. (Berlin: Walter de Gruyter und Co., 1938.) 1.62 gold marks.

THIS slender little volume covers much more ground than would be expected from its size. In addition to the usual elementary account of ordinary differential equations of the first and higher orders, including existence theorems, solution by series, and singular points, there is a chapter dealing with boundary value problems. This deals with Green's function, Sturm-Liouville expansions, proper values, and periodic boundary value systems. An appendix discusses the dependence of solutions of a system of differential equations upon a parameter, and upon the initial values of the variables.

Le superficie razionali

Per Fabio Conforto. Pp. xv+554. (Bologna: Nicola Zanichelli, 1939.) 80 lire.

THE present treatise is divided into two parts; the first, which occupies less than half the volume, is devoted to a systematic exposition, from the modern point of view, of the quadric, the cubic surface and the rational quartic surfaces. Here the reader will find a résumé of the classical results due to Cremona, Clebsch, Noether and others, with the various adjustments that critical considerations have necessitated. The second part deals with general theory; beginning with Noether's theorem on surfaces containing a pencil of rational curves, it proceeds to the discussion of surfaces having rational or elliptic sections, and thence to plane involutions and rational double planes. Of the latter important topic, the author gives a detailed account, the first that has ever appeared in book form. The work concludes with a chapter on Castelnuovo's theorem concerning the rationality of plane involutions.

As the author states in his preface, the work is based on lectures given by Prof. Enriques at the University of Rome; and in fact the book bears the hall marks of the collaborations (Enriques-Chisini, Enriques-Campedelli), which have provided the present generation of geometers with its standard text-books. There is the same leisurely exposition, interspersed with interesting historical information and critical notes, and the co-ordination of the material testifies to the master's skill. The work will be a valuable reference-book for every teacher of geometry.

Medicine

Vāgbhaṭa's Aṣṭāṅgahṛdayasaṃhitā

Ein altindisches Lehrbuch der Heilkunde, aus dem Sanskrit ins deutsche Übertragen mit Einleitung, Anmerkungen und Indices. Von Dr. Luise Hilgenberg und Prof. Willibald Kirfel. Lief. 5. Pp. 257–320. Lief. 6. Pp. 321–384. Lief 7. Pp. 385–448. (Leiden: E. J. Brill, Ltd., 1939.) 3.50 guilders each.

THESE three tracts form more instalments of Hilgenberg and Kirfel's scholarly translation from the Sanskrit into German of Vāgbhaṭa's treatise on medicine, the earlier parts of which have been noticed in NATURE.

The first half of Part 5 continues the discussion of the etiology and symptoms of diseases, such as boils and erysipelas, skin diseases including leprosy, abdominal swellings, which it is noted may be due to enlargement of the spleen, and rheumatism. Under rheumatism, the pain, stiffness and lameness, the involvement of the joints and of bone, are all mentioned.

The remainder of Part 5 and Parts 6 and 7 deal with treatment, mostly medicinal. The remedies prescribed are for the most part herbal ones, and have been identified by the translators; mineral remedies scarcely appear, and mixtures containing mice and other unpleasant ingredients, so commonly used in medieval medicine, are the exception. Another part should complete this work.

Modern Anæsthetic Practice

Edited by Sir Humphry Rolleston and Dr. Alan A. Moncrieff. (The Practitioner Handbooks, No. 3.) (Published on behalf of *The Practitioner*.) Pp. 231. (London: Eyre and Spottiswoode (Publishers), Ltd., 1938.) 10*s.* 6*d.* net.

THIS work consists of twelve articles, six of which had previously been published in *The Practitioner* and have since been revised by the authors, while six are new contributions. Every aspect of the subject has been discussed, including volatile anæsthetics, nitrous oxide anæsthesia in surgery, basal anæsthesia, endotracheal anæsthesia, spinal anæsthesia, anæsthesia and analgesia in midwifery, anæsthesia in the child, anæsthesia in dentistry, local anæsthesia and analgesia, the anæsthetic aspects of post-operation care, and the risks of explosion, so that the aim of the book to provide a practical manual for the general practitioner in his daily work has been admirably fulfilled.

Man against Microbe

By Prof. Joseph W. Bigger. Pp. 304+18 plates. (London: English Universities Press, Ltd., 1939.) 7*s.* 6*d.* net.

PROF. BIGGER, who is professor of bacteriology at Trinity College, Dublin, and author of a standard work on the subject, has set out to give educated readers who are not necessarily scientific investigators some idea of the nature of microbes, the methods of their study and their effects. He begins with a fascinating account of the first microbiologist, Antony van Leeuwenhoek, and then discusses the meaning and history of microbiology and the relation of microbiology to mankind, including a lucid description of the work of Koch, Pasteur, Ehrlich, Metchnikoff, Theobald Smith and Bordet among others. The text is liberally interspersed with portraits, illustrations of bacteriological equipment and microphotographs, and a glossary is appended. The work is written in an easy and familiar style, admirably suited for the class of readers for whom it is intended.

Brompton Hospital Reports

A Collection of Papers recently published from the Hospital. Vol. 7, 1938. Pp. iv+207+39 plates. (London: Brompton Hospital, 1939.) 5*s.*

BESIDES the annual medical report of the Hospital, this volume contains twenty articles, of which all but two, describing a method of inducing artificially selected collapse in pneumothorax therapy and an exhaustive account of the cauterization of pleuro-pulmonary lesions, have been published elsewhere. The other articles deal with various aspects of pulmonary tuberculosis, pneumonia and bronchiectasis, artificial pneumothorax, obstruction of the trachea, thoracoscopy and cauterization of adhesives, radiology and the surgery of inflammatory lesions of the lungs, cardiac emergencies and the prevention of minor ailments. The indexes of authors and subjects for vols. 1–7 are included.

Medicine in Modern Society

By David Riesman. Pp. vii+226. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1938.) 11*s.* 6*d.* net.

IN this work, which is based on his Vanuxem lectures delivered at Princeton University, Dr David Riesman, formerly professor of clinical medicine and now occupying the chair of the history of medicine in the University of Pennsylvania, has given the layman a clear and comprehensive account of the progress of medicine in the nineteenth and twentieth centuries and of the various problems which have arisen during that period. The subjects discussed include cancer, medical education, the prevalence of neurosis, superstitions and cults, with special reference to homœopathy, osteopathy and chiropractic, medicine as a career, the family doctor, medical ethics and preventive medicine.

Recent Advances in Forensic Medicine

By Dr. Sydney Smith and Dr. John Glaister. Second edition. Pp. viii+264+16 plates. (London: J. and A. Churchill, Ltd., 1939.) 15*s.*

THE principal subjects discussed in this well-known work, which should prove indispensable alike to medical jurists and barristers, are the diagnosis of injuries from projectiles, the identification of firearms, the examination of powders and the products of their production, the medico-legal application of the precipitin and other tests based on the action of precipitins and the individuality of the blood. The chief additions to the new edition, which contains seventy more pages and nineteen more figures than the last, are the incorporation of recent work on blood grouping, a chapter on the cuticular scales of hair by Prof. Alan R. Moritz of Harvard University, enlargement of the chapter on spectroscopy in medico-legal work, important additions to the chapter on alcohol in the blood, including an account of Widmark's method, and a note on larval infestation and putrefaction by Dr. A. G. Mearns.

Miscellany

If War Comes (an Essay on India's Military Problems)

By B. P. Adarkar. Pp. 41+xxxii+306+19 plates. (Allahabad: The Indian Press, Ltd., 1939.) 2.8 rupees.

THE central theme of this essay on problems of defence in India from the Indian point of view is that India's only hope of safety lies in full partnership and co-operation with Great Britain. The author argues that Indian and British interests are essentially the same in a world war, and that for India to remain outside, even if allowed, might merely result in her falling under a fresh foreign dominion. If, however, India needs Great Britain's help in defence he urges that Great Britain needs the help which India's man-power and natural resources could contribute. The effect of the rapidly changed conditions of modern warfare upon the individual problems of the defence of India is discussed, and Prof. Adarkar in a series of chapters urges the planning of Indian defence to ensure the most effective co-operation between Indian and non-Indian on terms of mutual respect, the efficient utilization of Indian resources and the stimulation of industry, trade and transport in India on lines designed to render her less vulnerable and more self-supporting or independent in the event of hostilities.

If his book is intended to bring home to his countrymen the reality of their danger it equally makes an appeal to Great Britain for yet more generous treatment the sincerity of which cannot be doubted. The community of interest between Great Britain and India offers an opportunity of developing yet further the spirit of national service, good will and co-operation which may overcome the difficulties in the way of full self-government whether from Hindu-Moslem jealousies, the problem of the Native States or embedded prejudices of the Services.

Gems and Gem Materials

By Prof. Edward Henry Kraus and Prof. Chester Baker Slawson. Third edition. Pp. xiii+287+4 plates. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 21*s*.

"KRAUS and Holden" has now become "Kraus and Slawson", as Prof. Kraus has been assisted in the preparation of this third edition of the book by Dr. Slawson, Dr. Holden having unfortunately died before the publication of even the first (1925) edition.

The features which have formerly made the book so popular have been still further strengthened, and there are twenty-seven additional pages and nineteen more illustrations in the text. The most immediately obvious improvement is the incorporation of four fine coloured plates of gem-stones, which originally appeared in Eppler's "Edelsteine und Schmucksteine". The chapters on cutting and polishing and on synthetic stones have been expanded and are now exceptionally good, and a short but useful chapter has been added on the metals used in jewellery.

Most of the small inaccuracies which were found in previous editions have now been corrected, but some still remain; notably in the diagram of absorption spectra and in the density figures given for synthetic and natural spinels. In the figures given throughout the book for specific gravity and refractive index the authors favour the broad values of the mineralogist rather than the more exact values which are often of diagnostic importance to the gemmologist.

Thanks to the clarity of the writing, the wide range covered by the book, and its many illustrations, "Gems and Gem Materials" is one of the most attractive texts on the subject that has yet appeared. It is a pity that so liberal a use of illustrations must inevitably entail a price which the needy jeweller's assistant will find it difficult to afford. B. W. A.

Evidence of Identity

By Kenneth Richmond. (Psychical Experiences Series.) Pp. viii+112. (London: G. Bell and Sons, Ltd., 1939.) 3*s*. 6*d*. net.

THIS is another of the short text-books on psychical research which have been recently issued to supply a demand for material of better quality than that usually provided by the majority of writers on spiritualism. The examples selected are mainly based upon cases collected and examined by the Society for Psychical Research, and thus their evidential value is somewhat enhanced.

In the present volume, Mr. Richmond is concerned with the question of identity, not so much from the point of view of the survival of personality after death as from that of the problem of the means by which any kind of identity can be established when considered in relation to mediumistic communications. In the course of his discussion, the author makes no attempt to minimize the difficulties involved; and his treatment will go some way to curb the enthusiasm of the uncritical believer and the seeker after miracles.

Apart from the fact that Mr. Richmond seems to lay a somewhat undue stress upon the rather dubious evidence supplied by the well-known American "Livre des Revenants", this little book is a good example of the work undertaken by the more sober among psychical researchers, and the author is to be congratulated upon the general level of criticism that he maintains throughout. A short glossary of terms most commonly used is appended, but there is no index.

Guide to Business Management Books

By G. E. Milward. Seventh edition. Pp. xiv+124. (London: Management Library, 1939.) 5*s*.

THE seventh edition of the *Guide to Business Management Books*, 1939, has been issued in cloth binding. It includes all notable books published during the six years up to and including November 1938. The Guide is arranged on the same lines as previous editions and the more outstanding books of 1938 are listed separately in the preface. The courses of reading printed in the Guide have again been expanded and are particularly adapted for staff training, although the biographical section might well be developed further, and include special studies which illustrate merits or defects of management in practice. A serious defect which should be rectified in subsequent editions is the absence of any dates of the editions of the works included.

The Subject Index to Periodicals, 1938

Pp. xxix+544. (London: The Library Association, 1939.) 70*s*.

THIS index, issued by the Library Association, is arranged under subject headings in alphabetical order, chosen from the alphabetical subject headings in the Library of Congress, U.S.A., with modifications and additions to suit British practice. With some important exceptions, periodicals covered by the *Agricultural Index*, *Engineering Abstracts*, *Engineering Index*, *Index Medicus*, *Journal of the Society of Dyers and Colourists*, *Photographic Abstracts*, *Science Abstracts*, *Journal of the Textile Institute*, *Royal Meteorological Society Bibliography* and the *Revue de Géologie, Minéralogie et Crystallographie* are not included. The location list first published in the 1937 volume has been retained and gives valuable information regarding the periodical holdings of more than a hundred and seventy of the national, municipal and institutional libraries in the United Kingdom. The locations are tabulated in seven columns, each covering a large area of the country, but the inclusion of a library in the location list implies no guarantee that it is prepared to issue periodicals to outside borrowers. Brief annotations are given where the titles do not sufficiently indicate the subjects of articles, but verse and fiction are not included. Under each heading, articles are arranged alphabetically by authors' names.

Iceland Papers, Vol. I

Scientific Results of Cambridge Expeditions to Iceland, 1932–38. Pp. vii+17 papers. (London: Oxford University Press, 1939.) 21*s.* net.

THERE is no better training for young men than to send them away from their families and teachers, giving them jobs that they feel to be incursions into the unknown. Such was the idea of the geographers of Oxford and Cambridge, but they found themselves restricted by university terms to the summers. Work in North Africa and to the South could be carried on at any season, but only in summer could the north be attacked. In consequence, we see year by year parties from Oxford going to Spitzbergen and from Cambridge to Iceland, while both universities, often using more experienced seniors, visit Greenland.

Geography includes nearly all science, and nothing comes amiss. In no section can much be accomplished in one northern season, and the torch is passed on from one party to another and so knowledge accumulates. In a series of separata, bound up together, we have the results of twelve Iceland visits from 1932 to 1938, usually two or three men together. They comprise five devoted to physical geography, six to birds, four oddments concerning spiders, worms, Collembola and freshwater algæ, and two stronger accounts of the Central Desert and of Grimsey Islet, necessarily on botanical lines.

We wish success to these ventures, and we approve of Iceland, for great profit may be foreseen in similar summer expeditions for several decades.

L'Année psychologique

Fondateurs: Henry Beaunis et Alfred Binet. Publiée par Prof. Henri Piéron. (Bibliothèque de philosophie contemporaine.) Année 37 (1936). Tome 1. Pp. xxiii +448. Tome 2. Pp. 449–844. (Paris: Félix Alcan, 1937.) 150 francs.

THIS yearly publication is always eagerly expected by psychologists, for it gives an accurate account of the research made in the various fields of psychology during the year. Reviews of books and of special articles are listed according to their subject; and the principal points in them are clearly explained. A series of specialized contributions add to the interest of this survey. In this issue might be mentioned those of Geblewicz and Shen (Rôle du temps dans la perception de la profondeur), of H. Piéron (Types d'intelligence), and of Fauville, Dewyn and Ellis (Aptitudes motrices et aptitudes perceptives).

T. G.

Urmass und Schöpfung

Neuentdeckte Gesetzlichkeiten. Von Ernst P. v. Schoen-Wildenegg. Pp. viii+235. (Berlin: G. Schoenfeld's Verlagsbuchhandlung, 1938.)

THE author investigates the origin of our system of numbers on the basis of biological facts. He attempts to prove the dominating existence of the geometrical progression in living beings as well as in celestial phenomena. Investigating and confirming some well-known facts, such as the distribution of the planets, he derives a number of empirical relations between the bodies of the solar system. Apart from this section of the book, which bears quite a personal note, the book as a whole is quite stimulating to read for all those interested in the physical and biological foundation of our past and present concept of measurement and number.

Animal and Bird Painting

The Outlook and Technique of the Artist. By Charles Simpson. Pp. viii+136+68 plates. (London: B. T. Batsford, Ltd., 1939.) 10*s.* 6*d.* net.

AN eminently readable book. The domain of animal painting has been little invaded by the 'wild men' of modern art, who would possibly be annoyed by the author's insistence on sincere observation, not only of animal structure and movement, but also of the landscape environment. Different classes of animals are treated in some detail, with short accounts of their origin and varieties. The student of animal painting will find help in the author's references to the particular snags and difficulties in the matter, and in his very practical advice on the method of catching and memorizing a special aspect of a moving subject. Considerable attention is given to the correct sequence of movements in walking and running animals. The influence of light in eliminating detail must not prevent close representation of essential form and solidity. Many paintings of animals should be called studies merely, in that the extreme details of anatomy are allowed to obscure the values in the picture as a whole.

The book is well and copiously illustrated by black-and-white reproductions of the works of old and modern masters of animal painting.

Physics

Physics for Technical Students

Sound, Electricity and Magnetism, Light. By Prof. W. B. Anderson. Third edition. Pp. x+361–796. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 15*s.*

THE stumbling block for many advanced technical students is inadequacy of training in fundamental physics. Physics is undoubtedly a subject in which, to the physicist, there can be no compromise; for the man who is to become one of a number of kinds of engineer and not a physicist, there is much to be gained by selecting those aspects of physics which are likely to be of greater use to him than other aspects. What these aspects are experience must tell; technology is daily becoming more scientific and an adequate syllabus must be continuously brought up to date.

The present text-book is along the right lines, but may not be entirely suitable for English engineering students. One thing that might have been done to improve its detail would have been the collaboration of a scientifically trained engineer, who would have introduced a greater conformity with the language of technology, so that the ideas may be more easily grasped by a technical student. Nevertheless, the author's work is very suggestive in forming fundamental treatments of physical phenomena for students specializing in applied science rather than in science itself.

L. E. C. H.

Motion Picture Sound Engineering

A Series of Lectures presented to the Classes enrolled in the Courses in Sound Engineering given by the Research Council of the Academy of Motion Picture Arts and Sciences, Hollywood, California. Pp. xviii + 547. (London: Chapman and Hall, Ltd., 1938.) 30*s.* net.

THIS text is the successor to "Recording Sound for Motion Pictures", compiled by some twenty authors and edited by Lester Cowan. In the distant days of 1931, the pioneer technicians of a new industry, that of adding sound to scene, had a great deal of what was new to say; their effort in print was by no means perfect, but it gave the impression of vitality and freshness. In the present publication we do not get a complete view either of the industry or of studio technique. The latter has changed extensively in the last decade, but we cannot judge what in the older book is now obsolete and what is now of primary importance. That is not to say that the first 175 pages are not valuable. They deal lucidly with technical solutions of many difficult practical problems which confront the recording engineer.

In a highly competitive industry, research has in recent years been on a co-operative basis, directed by the Research Council of the Academy of Motion Picture Arts and Sciences, which, through committees of experts, has sorted out the problems and used the best resources of the industry; the description of the results obtained gives an air of finality to the attainable criteria prevailing at the present time and that there is not much more to be done until there is another upheaval in the industry, such as the adoption of stereophony.

From the general acoustic point of view, great importance must be attached to the specification and realization of a standard of radiated sound reproduction, against which commercial systems can be compared and assessed in respect to their defects. The radiating system comprises two parts, one a cellular horn covering the range 300 c.p.s., to 10,000 c.p.s., driven by a phase-adjusted duralumin diaphragm, the other a set of large cone diaphragms operating through a horn terminated with a large baffle. The response results in a fluctuation within two decibels over the range 50 to 8,000 c.p.s., over a horizontal angle of nearly 110 degrees and a vertical angle of 60 degrees, with a maximum electro-acoustic efficiency approaching 50 per cent. The amplitude distortion and flutter specified in the reproducing machine and radiator set new standards for sound reproduction. The new types of push-pull recording on film, the control of the noise-level, microphones, and the new types of photo-electric cell which are required to reproduce the push-pull sound-tracks are very well treated. Film processing is rather less well done than before.

The remaining three hundred pages do not carry the subject much further, because attention is diverted to details of electrical circuits, such as transformers and filters and elementary circuit theory, which appear to have been included solely because they happened to fall into a series of lectures to film technicians as a part of their education. The only part which is not done better elsewhere by specialists is the section on properly designed equalizers; the dividing networks are new, and have been forced into reproducing circuits by the necessity of operating loudspeaking receivers in series or parallel without overloading them with currents of frequencies for which they are not intended to have appreciable response. One concludes that there is good material in the present text, but it has been made expensive by the inclusion of much extraneous elementary matter.

L. E. C. HUGHES.

Textbook of Heat

By Dr. R. Wallace Stewart and Dr. John Satterly. Revised by C. T. Archer. Second edition. Pp. vii + 410. (London: University Tutorial Press, Ltd., 1939.) 7*s.* 6*d.*

THIS is a book on the theory of heat written for students of the standard of the intermediate university examinations. It appears to fulfil its function admirably, and should afford an excellent introduction to the more advanced works on thermodynamics. There is no great originality of treatment, but all the usual branches of heat are dealt with in an adequate manner. The type used is clear, and the text is well illustrated by more than two hundred bold diagrams. The large selection of questions taken from recent examination papers of the University of London should prove useful to students.

Ions, Electrons and Ionizing Radiations

By Prof. J. A. Crowther. Seventh edition. Pp. xii + 348 + 7 plates. (London: Edward Arnold and Co., 1938.) 12*s.* 6*d.* net.

THE seventh edition of this well-known book is to be welcomed, for in it the author has been enabled to give an account of some of the more recent developments of the rapidly changing subject of atomic physics. Experiments on the structure and disintegration of the nucleus are described, including those made by means of the cyclotron, and there is also a discussion of the production of the artificial radio-elements such as radio-sodium and radio-phosphorus. The section on cosmic radiation has also been rewritten and enlarged. Prof. Crowther possesses the gift of lucid explanation, and it suffices to say that the additions now made reach the same high standard as the remainder of the work.

30: Mars on September 23. Mars, Jupiter and Saturn are the triad of evening stars. Mars, post-opposition, decreases from mag. − 1·8 to mag. − 1·1. Jupiter is in opposition on September 27 and reaches its greatest brightness (mag. − 2·5). Close groupings of Jupiter's four inner satellites are seen at 0h. 15m. on September 5 (satellite II in eclipse), 6, 13, 23, and 30. The ring system of Saturn has now reached its most open phase for this year. The variable star, Algol, is well placed for observation all night. The Pleiades rise in he late evenings "like a swarm of fireflies tangled n a silver braid". The chief interest, however, on clear moonless nights in autumn is the region of the Milky Way. Apart from its remarkable structure—star clouds, dark rifts and "coal sacks", and gaseous nebulæ, the galactic plane is also the preferential region for classes of stars of peculiar interest, novæ Cepheid variables and O-type stars. In the direction of the rich fields of Sagittarius lies the centre of our stellar system more than 30,000 light years away and obscured from sight by absorbing tracts of cosmic dust and of gas. Tracing a path slightly inclined to he Milky Way is a belt of bright stars that includes he brightest stars in Orion, Taurus, Cassiopeia, Cygnus and Lyra. These stars and others of the brighter *B*-type and *A*-type are representatives of a relatively small local cluster that is some 2,000 light years in diameter and contains the solar system. The average star density of the Milky Way fields is about 40,000 stars per square degree; towards the poles of the galaxy the density falls to about 1,200 stars. The 100-inch telescope at the Mount Wilson Observatory has recorded with exposures of 200 minutes on fields at the north galactic pole as many recognizable nebulæ per unit area of the sky as stars! These emote stellar systems are exemplified by the great Andromeda Nebula visible to the unaided eye as a hazy patch near the star ν Andromedæ.

Announcements

AT the first meeting of the Council of the newly formed Gas Research Board of the gas industry, it was announced that the first president of the Board would be Sir David Milne-Watson. The appointment f the secretary of the Institution of Gas Engineers s the first secretary of the Board was confirmed.

THE Médical Research Council has appointed Dr. Donald Hunter, physician to the London Hospital, and Mr. Harold E. Clay, national secretary of the Passenger Services Group, Transport and General Workers' Union, to be members of the Industrial Health Research Board, in succession to Prof. J. A. Dixon and Mr. R. Coppock.

THE College of Physicians of Philadelphia has warded the Alvarenga Prize to Dr. Harry Goldblatt, rofessor of experimental pathology and associate irector of the Institute of Pathology, Western Reserve University, Cleveland, Ohio, for his outstanding contributions to the pathogenesis of hypertension.

A REPRESENTATIVE body of members of the Institution of Civil Engineers is sailing from Liverpool on August 26 to participate, at the invitation of the American Society of Civil Engineers, in a British-American Engineering Congress opening in New York on September 4, and to visit the World's Fair and various places of engineering interest. The party numbers about a hundred, coming not only from Great Britain but also from India, Australia, South Africa, Nigeria, Iran and Palestine, under the leadership of Mr. W. J. E. Binnie, president of the Institution. It is thirty-five years ago since an official visit to America was made by members of the Institution.

THE fifty-second annual conference of the Sanitary Inspectors' Association will be held at Bournemouth on September 4–9 under the presidency of Mr. J. C. Dawes. Further information can be obtained from the secretary, 18 Grosvenor Place, London, S.W.1.

THE American Association of Biophysics and Cosmobiology is organizing an international congress of biophysics, biocosmics and biocracy to be held in New York on September 11–17 with Prof. D. Arsonval, Branly, Langevin and Tchijeskvy as honorary presidents. Further information can be obtained from the general secretary, 39 rue Scheffer, Paris 16^{e}.

THE seventh Congress of the French Society of Phoniatrics will be held on October 17 at the Paris Faculty of Medicine when Dr. Pichon and Mme. Borel-Maisonny will read a paper on aphasia and psychogenic disorders of speech. Further information can be obtained from the general secretary, Dr. Tarneaud, 27 avenue de la Grande-armée, Paris 16^{e}.

A EUROPEAN Conference on Rural Life will be held under the auspices of the League of Nations in Geneva during October 16–31. The Conference will be devoted to the well-being and solidarity of European rural life. Preliminary information, national monographs and technical documentation are being published in this connexion by Messrs. Allen and Unwin, 40 Museum Street, London, W.C.1. Further information can be obtained from the Secretary, League of Nations, 16 Northumberland Avenue, London, W.C.2.

A QUARTERLY review of philosophical books and periodicals in the form of brief excerpts and synopses will make its appearance in the early part of October of this year under the title *Philosophic Abstracts*. The intention is not only to present English-speaking philosophy departments with a bibliography of essential philosophical literature, but also to give them an opportunity of keeping abreast with the principal philosophical theories as presented by their respective authors. The editorial offices are at 884 Riverside Drive, New York, N.Y.

DR. HERBERT H. BROWN, one of the signatories of the letter entitled "Sponge Mortality in the Bahamas" which appeared in NATURE of May 13, p. 807, has written pointing out that his name is incorrectly printed as "Hubert H. Brown" at the end of the letter.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 384.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Role of Dietary Choline in Neurohumour Production

THE lipotropic action of choline[1] and the role of choline in the formation of acetylcholine have not hitherto been studied in the same experimental animals. It seems reasonable to suppose, however, that, in addition to the production of the familiar fatty liver, lack of dietary choline might result in deficient formation of the neurohumour, acetylcholine. The findings in preliminary experiments[2] suggested that this is indeed the case.

The present experiments were designed to test the hypothesis that a diet poor in choline results in a low level of vagus activity and that this in turn is due to deficient formation of acetylcholine at the nerve endings. Rats were used as experimental animals, and were kept on the various diets for at least nine weeks. Vagus activity was evaluated by observing the slowing of the heart brought about by electrical stimulation (twelve impulses per second at maximal strength) of the distal cut end of the left vagus nerve. The resting heart-rate in rats (170–250 gm.) under urethane anæsthesia on a normal diet is from 300 to 500 beats per minute. The heart rate of animals on a low-choline diet or of those receiving the same ration with added choline fell within these limits. In one series of animals vagus stimulation reduced the heart-rate to approximately 30 per cent of the normal value in rats on a normal diet, to 45 per cent in rats on a low-choline-plus-choline diet and to 75 per cent in the animals on a low-choline diet. In other series many of the rats on the low-choline diet showed a normal vagus effect but others, as seen consistently in the small series cited above, showed very little change in heart rate on vagus stimulation. The most suggestive finding of this investigation is that, in animals on a low-choline diet showing little effect of vagus stimulation, the intravenous administration of choline (0·5 c.c. of 2 per cent choline chloride) increased this effect. This phenomenon was never seen in rats on a normal or low-choline-plus-choline diet.

We conclude that deficient vagus function may be linked with a low intake of dietary choline and this may, in part at least, be rectified by injected choline. It is therefore reasonable to suggest that choline deficiency may result in deficient formation of acetylcholine at the nerve endings. This and other possibilities are to be tested further in subsequent experiments in which it is hoped that dietary conditions producing an even more drastic deficiency of choline may be utilized.

Effect of Lipoid Solvents on Vaccinia Virus

THE elementary bodies of the dermal strain o vaccinia virus can be obtained readily from the skir of the infected rabbit's back in suspensions showin a high degree of physical and immunological homogeneity; the virus contains protein, carbohydrat and ether-soluble lipoid material[1]. We find that after drying and extraction with benzene or ether the dry density is increased from 1·26 to 1·31 and i is possible to redisperse the virus residue by mechanica grinding in buffer solution. The appearance by darkground examination and the sedimentation constan of the resuspended virus particles are unchanged, anc the boundary inhomogeneity is slightly reduced. Th infectivity of the virus is unaltered by this treatmen and it is therefore probable that the lipoid materia extracted with ether (consisting largely of cholestero and acetone-soluble fat) is derived from the host anc adsorbed on the virus.

The ether-extracted virus still contains 9 per cen of lipoid material, containing some 2 per cent phosphorus, which can be extracted only with alcohol o alcohol-ether mixtures. The virus residue after treatment with alcohol has almost entirely lost its infectivity, but it is impossible to say whether this i due to the removal of the lipoid material or to th concomitant effect of alcohol on the virus protein The virus residue now has a density of 1·36 and suspensions give completely inhomogeneous boundarie in the centrifuge. It contains 15·5 per cent nitroge and 0·7 per cent phosphorus. Colorimetric carbohydrate estimations (total carbohydrate[2], orcinol-HC pentose test and Feulgen reaction) indicate th presence of approximately 3 per cent thymonuclei acid and 4 per cent carbohydrate; tests for glucosamine after acid-hydrolysis were positive.

Washing the virus repeatedly with water or dilut buffer, which is known to result in the liberation o specifically precipitable protein[3], was found to remov nitrogen, phosphorus and carbohydrate but no nuclei acid. If the ether-extracted virus is treated with 1 pe cent sodium carbonate at 20°, practically all th nucleic acid and 40 per cent of the carbohydrate pas into solution in 1–2 hours. This effect is followed by gradual disintegration of the residue into particle of widely different sizes, some only slightly smalle than the original.

Though in its chemical and immunological complexity vaccinia virus approaches more nearly to th bacteria than to the plant viruses, there appears t us to be little evidence that the substance of the viru is held within a cell membrane. The evidence whic has been given[4] of osmotic swelling (derived indirectl from measurements of sedimentation rates in medi of different density) is open to serious objections and such swelling can be observed in protein gel There is no evidence of selective ion permeabilit nd the resistance of the virus particle to attempts t mechanical disruption, to drying and to the action f ether militates against the idea of a fluid cytoplasm onstrained within a membrane. The piecemeal disntegration of the virus particle in sodium carbonate olution suggests to us that the virus has a gel-like bility to preserve its form, in which the nucleic acid nd perhaps also the bound lipoid present play an ssential part. The analogy with a protein gel is ot altogether satisfactory however since, although here is evidence[5] that much water is associated with he virus, the mechanical properties and the intense ight scattering suggest that this water belongs mainly o an ion atmosphere and not to the central particle.

This work has been carried out in collaboration vith Dr. C. R. Amies and Dr. G. H. Eagles; a full eport will be made later.

Effect of Ultrasonic Vibration on Vaccinia Virus

Earlier experiments by Hopwood and Gordon[1] howed that calf lymph vaccine virus retained its nfectivity after subjection to ultrasonic vibrations c. 500 kilocycles/sec.) and even appeared to have an ncreased infective titre. The increase was attributed o disengagement of virus from particles of inert naterial in the crude lymph. Rivers *et al.*[2] found hat sonic vibrations of considerably lower frequency 8,900 per second) applied for 15 minutes to purified uspensions of vaccinial elementary bodies resulted n a detectable reduction in their infectivity, and oted that adventitious substances, particularly proein, protected the virus from inactivation.

Using washed vaccinial elementary bodies of a abbit dermal strain, in every way comparable to ivers' preparations, we have dried the virus from he frozen state, extracted the 'adventitious' lipoid[3] ith benzene, and redispersed the elementary bodies ompletely with ultrasonic vibration, without loss of nfectivity.

The washed, dried and benzene-extracted virus as irradiated at 550 kilocycles/sec. in a thin-walled lass tube containing dilute phosphate buffer. Three uccessive exposures lasting 1¼ minutes were given, nd, by cooling the tube in ice between the exposures, he temperature was kept below 20° C. throughout. he milky suspension was centrifuged for 15 minutes t 3,000 rev. per minute, whereby about a third of he virus was deposited. The deposit was again radiated and centrifuged; after two or three epetitions of this treatment, more than 95 per cent f the original dry virus was found to have been ispersed. Intracutaneous inoculations in the rabbit howed no significant difference between the titres f the original undried virus and that of the virus ried, benzene-extracted, and resuspended, either by ltrasonic vibration or by grinding[3]. The microscopic ppearance of stained specimens, and of unstained specimens by dark-ground illumination, the sedimentation rate, and boundary homogeneity, were also unaffected by the ultrasonic treatment.

A Benzpyrene Tumour Strain in Hamsters with Tendency to Metastasis Formation

Experiments on the hamster with carcinogenic substances have so far been described only in a short communication by Gye and Foulds[1]. Our experiments were made with the view of demonstrating whether the tumours caused in the hamster by carcinogenic substances show any peculiarities with regard to formation and course. 40 hamsters (*Cricetus auratus*) were given subcutaneous injections of 0·25 c.c. of a 1 per cent solution of benzpyrene Meurice. 93 per cent of the animals developed tumours after a latent period of three months on the average. Histologically they were polymorph cell sarcomata.

Whereas we never observed metastases in rats with primary or transplanted benzpyrene tumours, we found these in a hamster tumour strain which we have been passaging since February 1938. The special features of this metastasis formation are: (1) the extraordinarily large number of animals which developed metastases; (2) the preference of metastases for lymph glands; (3) their spread through the greater part of the body. Of 54 hamsters sectioned, 39 (72 per cent) showed metastases. All the animals had metastases in the lymph glands. One animal had in addition a metastasis in one kidney. The process involved the axillary, groin and mediastinal glands and a chain of glands in front of the lumbar spine down to the pelvis. Mostly several glands are affected, but in many cases all the glands in the above-mentioned regions are involved. The axillary region and mediastinum showed the largest tumours. We are here, therefore, dealing with a dissemination resembling a systemic disease.

Splenectomy or complete irradiation of the whole body with X-rays does not noticeably increase the percentage of animals with metastases. In some cases it is possible to transmit tumours by the subcutaneous injection of blood from hamsters with metastases.

The spread of the tumours in our hamsters resembles the changes in the lymph glands of tumour-bearing mice described by Parsons[2]. This worker assumes that because transmission is effected through filtered cell-free material, dissemination is caused by a filterable agent. We have not yet completed transmission experiments with filtrates. But we have deprived gland material of cells capable of multiplication by means of X-rays by the method employed by Doljanski and Halberstaedter[3] in Rous sarcoma. Attempts at transmission with such material have so far been negative.

While it is not usual to find metastases in rats with primary benzpyrene tumours, Oberling and M. and P. Guérin[4] have succeeded in obtaining them by injecting very large quantities of benzpyrene. Injection of 75 mgm. of benzpyrene will cause metastases in 50 per cent of rats. Oberling and Guérin consider that this is due either to the fact that large doses of benzpyrene lower the resistance of the organs, or that the tumour cells produced by large doses are more aggressive and proliferative.

In our cases, the animals showing metastases did not come into contact with benzpyrene. It must be assumed that both the tendency to metastasis formation and the organ affinity in our tumour strain is based upon a peculiar property of the tumour cells themselves.

Lethal Action of Alpha-Rays on Sea-Urchin Eggs

When unfertilized eggs of sea-urchin, *Pseudocentrotus depressus* (A. Agassiz), are inseminated immediately after the irradiation with gamma- or beta-rays of radium, the time of their first cleavage is prolonged roughly in proportion to doses[1]. This phenomenon has the same tendency to that already reported by Henshaw[2] and others, who used roentgen rays and ultra-violet light. Recently, we have studied the effect of alpha-ray irradiation and obtained quite different results.

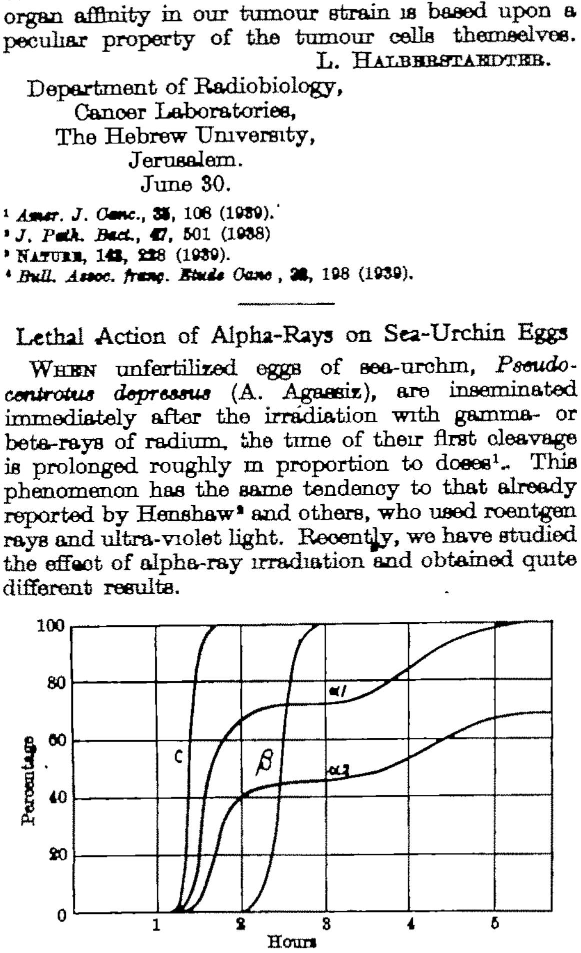

Fig. 1.

Curves showing the percentage increase of eggs in two-cell stage after insemination.

c: control; β: irradiated with beta-rays (30,000 r in one hour); a_1 and a_2 irradiated with alpha-rays (48 mc.-sec. in 10 seconds and 145 mc.-sec. in 1 minute).

The following experiment was made on the eggs of sea-urchin, *Strongylocentrotus purcherrimus* (A. Agassiz). Eggs were carefully placed in a single layer in a small dish, 7 mm. in diameter with a thin bottom of collodion film, less than 1 μ in thickness. Unde the dish a piece of glass with radium C′ was placed a the distance of 5 mm. As the range of alpha-ray of radium C′ in water is 60 μ, taking into considera tion the absorption of the air and the specific gravit of eggs, the alpha-rays are estimated to penetrat into the eggs as far as 51 μ. The diameter of the egg is about 90 μ. In every experiment the intensity o radium C′ activity was measured by electromete and the dose is expressed by millicurie-second, con sidering the decay of radium C′.

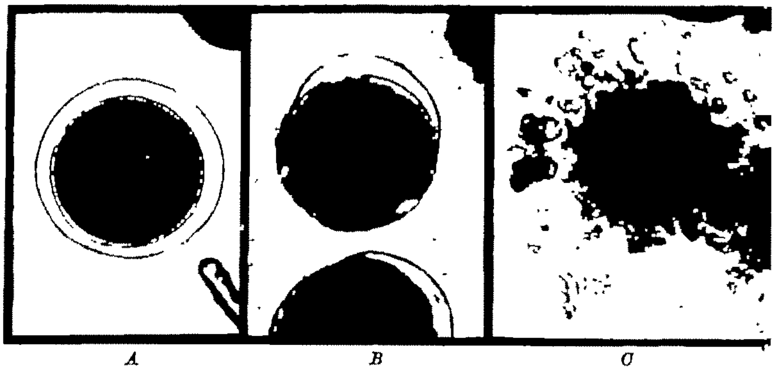

Fig 2.

Microscopic appearance of non-irradiated (A) and irradiated eggs in early (B) and complete (C) disintegration.

Fig. 1 indicates the increase of the percentage o eggs in two-cell stage produced by first cleavage wit the lapse of time after insemination. Curve C show control, curve β a case of beta-ray irradiation, an curve α_1 and α_2 two cases of alpha-ray irradiatio The eggs irradiated by beta-rays (curve β) take som time to begin cleavage and their cleavage goes o slowly, but the tendency resembles control. Smal doses of alpha-rays produce no effect on the cleavag time. Even after larger doses of alpha-rays (curve α_1 the beginning time of the cleavage is almost the sam as in control. (A very little prolongation shown i considered as the effects of beta-rays accompanied b alpha-rays.) Moreover, in this case the cleavag proceeds very fast at the beginning, but seems t stop when a certain percentage of cleavage is reache while after several hours it goes on very slowly agai Thus in the case of alpha-ray irradiation, some egg take the ordinary course of cleavage, while in othe the cleavage is delayed. With the increasing dose of alpha-rays, fewer cases of the ordinary cleavag are observed (curve α_2), and some eggs stop cleavag absolutely. Even the eggs producing fertilizatio membrane by insemination with normal sperm sto cleavage, and from about one hour after the irradia tion they gradually disintegrate, as is shown in Fig. This disintegration phenomenon can be seen in th same way in unfertilized eggs. This is death cause directly by alpha-rays.

We are indebted to Prof. M. Nagayo, Dr. B Yamakawa and Dr. W. Nakahara for their kin advice and encouragement.

Amino-Acids and Rooting of Cuttings

THE work of Went and co-workers and that of Zimmerman and his associates has amply demonstrated the value of the so-called 'root-forming' hormones. Went, Bonner and Warner[1] have shown that in certain cases vitamin B_1 treatment of hormone-treated cuttings has resulted in a great increase in the rapidity of rooting and in the number of roots produced. I have confirmed this finding in the case of one species, namely, *Camellia*, used by these workers, but it is apparent that the treatment with vitamin B_1 (aneurin) must be given at the appropriate time after hormone treatment. This period after hormone treatment is difficult to determine. In some instances response has been rapid and at other times no response to vitamin B_1 has been obtained, but the same cuttings may respond to later treatment.

White[2] has shown that certain amino-acids are essential for the growth of excised tomato roots. The amino-acids found necessary were: glutamic acid, lysine, histidine, phenylalanine, leucine, isoleucine, valine, serine and proline. Went and co-workers, referring to "essential amino-acids" in the paper[1] referred to above, predicted that "cuttings may be found in which root development is limited by these substances".

In the course of my experiments, a mixture of the above-mentioned amino-acids was used to treat cuttings which had just been treated with α-naphthalene acetic acid at a concentration of 1 part in 20,000 of water. The cuttings used were *Rhododendron Maddeni* var. *Jenkinsii*. Two concentrations of the amino-acid mixture were used. Solution I was made up to contain approximately the concentration of each amino-acid that was found by White to be the optimum for root growth. Solution II was ten times the concentration of solution I.

Treatment 1. Cuttings after α-naphthalene acetic acid treatment were kept with about ¾ in. in solution I in a heated frame at 22° C. for eight days (the amino-acid solution was changed twice during treatment).

Treatment 2. Cuttings soaked for twenty-four hours in solution II.

Treatment 3. Cuttings soaked in water for eight days.

Treatment 4. Cuttings soaked in water for twenty-four hours.

After treatment the cuttings were planted in sand.

After four weeks the cuttings from treatment 1 showed marked swelling of the base of each cutting accompanied by the splitting of the epidermis. There were no signs of callus formation. Cuttings from treatment 2 showed similar enlargement of the base but this was not quite so marked, while those from treatments 3 and 4 showed definite callus formation but no swelling of the base.

After six weeks all cuttings from treatment 1 (10 cuttings in all) were rooted. Six cuttings from treatment 2 were rooted—after seven weeks all were rooted. No roots were on cuttings from treatments 3 and 4, even after seven weeks, though callus formation was marked.

The results indicate that one (or more) of the amino-acids used has had a marked effect on the production of roots. This observation substantiates the prediction of Went *et al.* that rooting of some cuttings may be limited by lack of amino-acids.

Experiments to indicate which of the individual amino-acids was responsible for the observed effect are under way.

Hydrolysis of Starch Films by Polarized Infra-Red Radiation

IT was shown in 1924 that, in the presence of small quantities of diastase at room temperature, plane-polarized daylight has a selective effect in accelerating the hydrolysis of starch grains[1].

In the case of the temporary starch in the living leaf very marked evidence of hydrolysis was observed on irradiation with daylight polarized by a Nicol prism, a well-defined image of the prism aperture being obtained, when the irradiated leaf was treated with iodine solution[2].

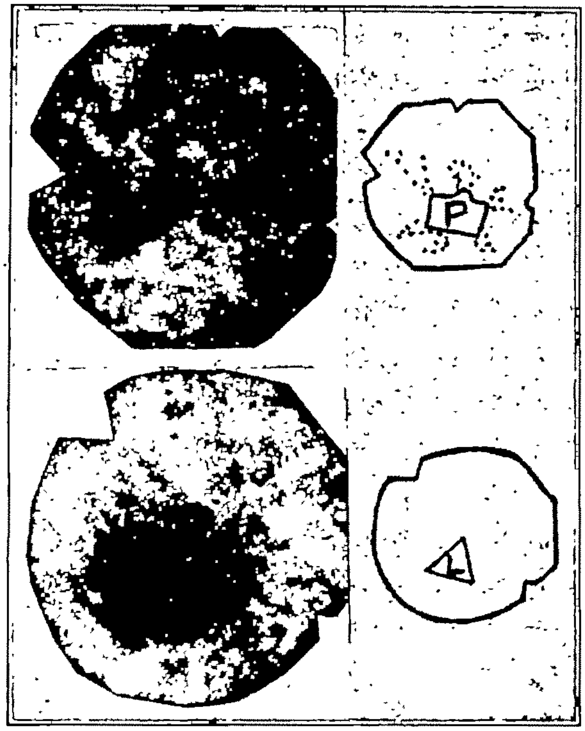
It was also shown that, when the stomata in the living leaf are irradiated with plane-polarized daylight, the rate of hydrolysis of the starch in the guard-cells is sufficient to burst them[3].

Furthermore, films of starch solution on glass and on filter paper were irradiated with plane-polarized light and convincing evidence of hydrolysis was obtained. The starch films on glass after irradiation deposited crystals on drying. The starch films on filter paper were treated with iodine solution after irradiation and the resulting blue colour was much less pronounced in those portions of the film which had been exposed to the polarized radiation.

In 1936 Prof. Baly directed my attention to the fact that carbohydrates do not selectively absorb rays in the visible and near ultra-violet regions of the spectrum, but selectively absorb rays in the wavelength region 1·5 μ–6 μ, and he suggested the use of polarized infra-red radiation.

The radiation from a roll of fine platinum gauze heated in a Bunsen burner was reflected upwards, (*a*) by a sheet of ferrotype at the polarizing angle, and (*b*) from a polished metal surface which had been lightly greased in order to reduce the intensity. These two reflected beams, one plane-polarized and the other non-polarized, irradiated moist starch films on filter paper in petri dishes. In each case a diaphragm with an aperture cut in it was interposed, the shapes of the two apertures being purposely different, as shown by the accompanying line diagrams.

After being irradiated for 2–3 hours, the starch films were allowed to dry in a dark room and then treated with iodine solution and *thoroughly* washed (to remove dextrins). As may be seen from the photograph (top) the effect of the polarized radiation is shown by a lighter coloured area which corresponds in shape to the aperture *A* in the diaphragm. The definition of this lighter area is somewhat marred by the diffusion of the products of hydrolysis into the non-irradiated area. It may be noted that this diffusion does not take place in the living leaf, owing to the starch grains being enclosed in cells, and



Starch films after staining with iodine (left). *P* shows diminution of starch, the dotted lines indicating streams of hydrolysed products. *L* shows condensation.

consequently the image of the aperture of the Nicol prism was much more clearly defined as stated above.

In the control shown in the lower photograph the reverse effect was observed with non-polarized infra-red radiation, the irradiated area giving a darker colour on treatment with iodine solution.

This result would seem to give definite evidence that starch is hydrolysed by polarized infra-red radiation.

I have to express my thanks to Prof. Baly and also to Mr. Riddell, director of the Folkestone Technical Institute, for the excellent facilities which enabled the observations with infra-red radiation to be made.

Reciprocal Hetero-Transplantation of Limb Primordia between Duck, Turkey, Guinea and Chick Embryos

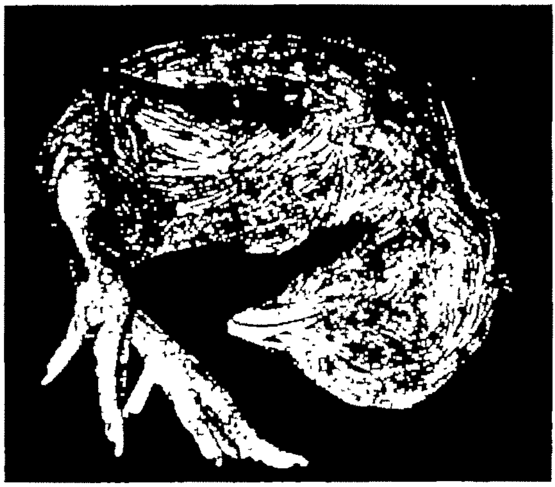
Successful transplantation of a chick limb bud to a turkey host was demonstrated by Eastlick[1] in 1939. Since that time, a number of grafts have been made by transplanting wing or hind limb primordia to the intra-embryonic cœlom or lateral body wall of a variety of hosts. Normal shaped limbs have been secured in reciprocal grafts made between chicken and turkey, duck and chicken, guinea and chicken, and turkey and guinea embryos.

That the limb primordia are self-differentiating is shown by the fact that many of the buds placed within the intra-embryonic cœlom develop although attached to the host mesenteries by only an artery and vein. In such cases the skeletal elements are well formed, but the muscles appear to undergo fatty degeneration. Other grafts attached to the flank of the host become innervated and seem to possess normal musculature.

While numerous examples of the above-mentioned types of grafts have been obtained, the majority of the hosts died before the time of hatching. This appears to be due to the fact that the grafts attached to the flank usually crowd the host within the shell and hence weaken it, while those grafts made into the cœlom seem to interfere with the retraction of the yolk sac. In five cases, to date, hatching has occurred and the birds have survived. One chick, killed 24 hours after hatching, was found to have a duck leg within its cœlom. A second chick with a duck leg attached to its flank still survives. The additional leg has a webbed foot and is in good proportion, with the exception of a missing toe. The leg seems to be innervated but cannot be flexed. This leg has increased in size since the time of hatching.

Three chicks have hatched with guinea legs attached to their flanks. All four of the above-mentioned chicks are being kept alive for further study. A number of turkey hosts bearing chicken legs and chicken hosts bearing guinea limbs have broken the shell but were too weak to survive.

Dorris[2] first reported that the melanophores of the fowl are derived from the neural crest. Eastlick[3] substantiated this observation by grafting limb bud of Barred Rock embryos to White Leghorn hosts. Those limb primordia, which included neural crest cells, developed pigmented down, while those from which the neural crest cells were excluded bore non-coloured plumage. Similar results have been secured in this study, since non-coloured plumage developed on limbs secured from mallard ducks, Bronze turkeys and Pearl guineas in those cases in which neural crest cells were not included with the transplant.



80-hr.-36-somite Bronze turkey limb bud transplanted to intra-embryonic coelom of 60-hr. 33-somite White Leghorn host. Host autopsied at 19 days. Transplant attached by narrow strand to mesenteries.

When neural crest cells were included with the limb primordia of Bronze turkey and mallard duck embryos and the transplants made to the flanks of White Leghorn chickens, it was found that the lateral body walls of the hosts became pigmented by the migration of donor melanophores. Such evidence of migration has not been observed when guinea limb buds containing neural crest cells were transplanted to White Leghorn embryos.

Fire-Fly 'Spinthariscope'

IT must be well known that the lantern of a firefly, teased by being held with the fingers, emits rregular flashes from minute point-sources in the antern which follow the normal flash, the light of which fills the entire lantern. I am wondering, however, if the very astonishing spectacle presented by a fly which has been bitten by a spider has been described. Within a few minutes after a few 'nips' have been made by the spider, if the fly is removed from the web, the lantern will be observed to glow with a faint green light which shows the same shimmering' quality as the radium paint on the dial of a watch. Examination with an ordinary hand magnifying glass, of moderate power, shows the antern filled with bright points of light, which at irst sight appear to be in rapid vibratory motion, and at the end of half an hour we have a seething cauldron of hundreds of bright points, dancing and flashing, and giving an almost perfect picture of a creen of zinc sulphide under a terrific bombardment of 'alpha' particles (spinthariscope). The phenomenon persists with undiminished intensity for forty-eight hours but finally dies out, the fly apparently having eturned to normal. The spinthariscope effect is frequently accompanied by an occasional normal flash, which ceases if the fly is decapitated, though he other effect continues. The normal flash of the antern is obviously due to the simultaneous excitaion of all the luminous centres by nerve impulses from the brain, but the scintillations persist even fter the lantern has been severed from the body. Both types of illumination cease if the fly is placed n a narrow glass tube through which a stream of carbon dioxide is flowing. I have produced the pinthariscope effect by innoculations with 1 : 1000 solution of snake venom, but in this case the fly id not recover.

Under a microscope, with a low-power objective, the individual flashes of green light are seen against black background and the strong vibratory movement seen with a hand magnifier appears to be due chiefly to the quenching of a flash at one point ccompanied by the successive flash of a luminous entre in its immediate vicinity. My impression is, owever, that I have seen single flashes quiver, hough in this case it may be merely the spreading of the chemical reaction which produces the light, rom one part of a cell to another. The phenomenon, een with the microscope, is really an amazing sight.

The spiders were, in most cases, small ones found n window webs, with bodies not much larger than grape-seed, and they usually make their first bites on the leg joints of the fly. The sparkling green flashes appeared first along the upper edge of one or both of the two lanterns, sometimes on one side only. The phenomenon then spread rapidly throughout the entire volume of the lantern. It seems possible that some information about the nervous system of the fly might be gained by recording the position of points innoculated by the spider and the point, or points, in the lantern at which the scintillations first appear, but the problem is one for a biologist rather than a physicist.

Role of Phosphate in Pyruvic Acid Dehydrogenation

DURING earlier work[1] on the problem of pyruvic acid dehydrogenation with *Bacterium acidificans longissimum* (Delbrückii), it was found that in the absence of inorganic phosphate no reaction took place, and at low concentrations of phosphate the rate of dehydrogenation was proportional to concentration. This indicated that inorganic phosphate must in one way or another participate in the reaction. Such a view was further strengthened when it was found that pyruvic acid dehydrogenation was able to promote adenylic acid phosphorylation[2]. The supplying of active phosphate by a dehydrogenation reaction had only been observed with the phosphoglyceric aldehyde dehydrogenation[3,4]. Recently Negelein and Brömel[5] were able to isolate as the primary product of this dehydrogenation a labile di-phosphoglyceric acid which they assumed to be either a 1-3-phospho- or a pyrophospho-compound, probably the former. The remarkable finding of Negelein and Brömel induced me to see whether during dehydrogenation of pyruvic acid to acetic acid an intermediary phosphate compound occurred.

Acetylphosphate was prepared from trisilver phosphate and acetylchloride according to the method of Kämmerer and Carius[6]. For the present no serious attempt has been made to isolate the assumed intermediate mono-acetylphosphate, but a solution containing a mixture of the mono-, di-, and tri-acetylphosphates, in addition to acetate, chloride, and some inorganic phosphate, was used for experiments with dry preparations of *Bacterium Delbrückii*. The average stability of the bound phosphate in the solution corresponded roughly to that of creatine phosphate. The content of bound phosphate was estimated by the early method of Eggleton for creatine phosphate.

In the following experiment the colorimetric method of Lohmann and Jendrassik was used, where acetylphosphate, like creatine phosphate, finally appears as inorganic phosphorus. 44 mgm. dry bacteria were used per vessel, in a total volume of 1·25 ml. containing 0·04 *M* fluoride. The suspension was shaken at 37·5° for sixty minutes in nitrogen :

	0·75 mgm. acetyl-P 4·0 mgm. adenylic acid	0·75 mgm. acetyl-P 0 1 mgm. adenylic acid	0·75 mgm. acetyl-P
Mgm. inorganic and acetyl-P	1·12	1·39	1·37
Mgm. pyrophosphate-P	0·35	0·09	0·10

The experiment shows that after incubation with adenylic acid about 30 per cent of the phosphate of the added acetyl-phosphorus appears in the pyrophosphate fraction, corresponding to a phosphorylation of about 25 per cent of the added adenylic acid.

From the results of this and similar experiments and the earlier work mentioned above, it is concluded that the dehydrogenation of pyruvic acid proceeds according to the following formulation:

$$\text{pyruvate} + \text{phosphate} - 2\text{H} \rightarrow \textit{acetylphosphate} + \text{CO}_2$$

$$\underset{\text{(or adenylic acid)}}{\textit{acetylphosphate} + \text{H}_2\text{O}} \rightarrow \underset{\text{(or adenosinepolyphosphate)}}{\text{acetic acid} + \text{phosphate}}$$

In investigations of pyruvic acid metabolism it has long been puzzling that, although the oxidative breakdown of pyruvic acid has been found to go through a stage corresponding to acetic acid, added acetic acid is inactive in systems oxidizing pyruvic acid completely. The intermediate formation of acetylphosphate provides a reasonable explanation for the 'active' acetate, and for various acetylation processes connected with the oxidative breakdown of pyruvic acid and carbohydrate, for example, acetylation of amino-acids[7] and of choline[8].

Further details will appear in vol. 7 of the Cold Spring Harbor Symposium on Quantitative Biology. Acknowledgment is made of a grant from the Ella Sachs Plotz Foundation.

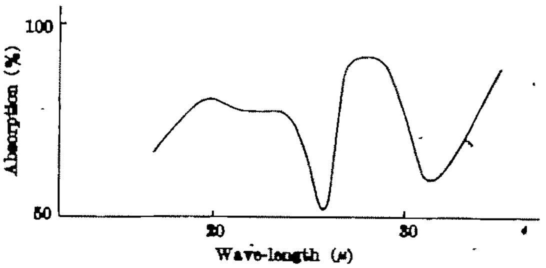
Structure of the Tetrachlorethylene Molecule

THE suggestion has been made by one of us that the vibration spectrum of tetrachlorethylene cannot be interpreted properly by a potential function involving only four or even seven force constants[1]. By considering the physical meaning of the 'cross-terms', a potential function was chosen the expression for which contained thirteen force constants, the values of which were determined from experimental data. The prediction was made that two fundamental frequencies, of symmetries A_1 and A_2 respectively, occur in the far infra-red, at 400 cm.$^{-1}$ and 346 cm.$^{-1}$.

Measurements have been made with the 'residual ray' apparatus, and with a grating spectrometer, described elsewhere[2]. The accompanying curve (obtained by the second method) shows the absorption in the region 30 μ, due to tetrachlorethylene dissolved in paraffin.



The frequencies of the two absorption bands are 387 cm.$^{-1}$ and 332 cm.$^{-1}$, in good agreement with the theoretical values. The slight differences may be due to the neglect of the anharmonicity and to the fact that the computed values refer to the gaseous and not to the dissolved state, as in our experiments.

From the above results, it is now clear that the frequencies in the spectrum of tetrachlorethylene cannot be correlated by means of a simple potential function as suggested before by one of us[3], and by Linnett and Thompson[4]. For example, a valency force field should give 604 cm.$^{-1}$ instead of 387 cm.$^{-1}$ for A_1.

On the other hand, it is still difficult to determine exactly the value of the C—C force constant because the interaction terms are insensitive to its variation. However, it may be substantially less than $8{\cdot}5 \times 10^5$ dynes/cm. as in ethylene; and the suggested structure arising from resonance between the C—C bonds is not to be excluded since the interaction terms of the form $f_C\ \Delta_{C-C}\ \Delta_{C-Cl}$ and $\gamma_C\ \Delta_{C-C}\ \Delta_{Cl-C-Cl}$ are very important ($\sim 1{\cdot}70 \times 10^6$ dynes/cm.).

Complete details will be published shortly elsewhere.

One of us (J. D.) wishes to express his thanks to Prof. C. Manneback for helpful correspondence during the preparation of the note on which the present one is based.

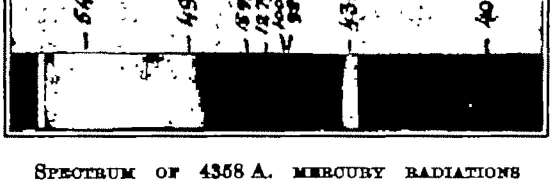
Structure of *p*-Diphenylbenzene and its Raman Spectrum

THERE have been very few structure determinations of aromatic compounds which contain three benzene rings. The structure of *p*-diphenylbenzene of the diphenylbenzene family has been studied by L. W. Pickett[1] by the method of trial and error and Fourier analysis, and this tends to show that the molecule of this compound is planar in form. In the present investigation our object is to attack the problem from a study of the Raman spectra of such compounds.



SPECTRUM OF 4358 A. MERCURY RADIATIONS SCATTERED BY SOLID *p*-DIPHENYLBENZENE.

In a previous note[1], one of us and S. Abdul Aziz have submitted the results of our investigation on the meta- and the ortho-compounds of this family. We have now also succeeded for the first time in obtaining the Raman spectra of *p*-diphenylbenzene in the solid state, and in spite of the very strong fluorescence shown on the plates, as the photograph reproduced here will show, the substance has yielded 24 new lines not recorded before. The frequencies obtained are at 3041(3), 2824(0), 2205(½), 2140(½), 2095(3), 2029(3), 1760(1), 1673(0), 1605 (10), 1592(10), 1549(3), 1503(1), 1372(0), 1274(10), 1219(6), 1148(0), 1039(1), 1008(4), 981(4), 811(0), 773(5), 598(½), 85(5), and 42(5) cm.$^{-1}$ respectively. (Intensities are given in brackets.)

p-Diphenylbenzene has three benzene rings joined in the *para* position, and the central ring with each of the end ones may be considered to constitute a diphenyl molecule. Diphenyl[2], which consists of two benzene nuclei joined end on by a C–C bond in the *para* direction, has been shown to be planar, and all the important frequencies found in diphenyl by one of us[3] and also by Wood[4] and others[5] are observed also in *p*-diphenylbenzene. These diphenyl frequencies are at 1610(10), 1590(8), 1544? (Wood), 1283(10), 1032(3), 1003(10), 980(1) and 779 cm.$^{-1}$ respectively. A comparative study of the spectra observed in these two compounds lends support to the view that the molecule of *p*-diphenylbenzene is planar in form.

Further investigation is proceeding and details will be published elsewhere.

Dunstan's Law

DUNSTAN'S law[1] for viscosity is given by

$$\log \eta = aM + b,$$

where η is viscosity of liquid at a definite temperature, say 20° C.; M is the molecular weight of the liquid; a is a general constant; and b is a specific constant characteristic for any one homologous series.

I have derived this law from theoretical considerations; but the important point is that this derivation also defines the limitations of the law in more rigorous manner. Andrade's equation is now universally accepted:

$$\eta = Ae^{B/T},$$

where A and B are constants and T is absolute temperature of measurements. A recent rendering of this equation is:

$$\eta = Ae^{\frac{Ml}{nRT}};$$

where l is the latent heat of vaporization, and n is a characteristic constant between 2·5 and 4·0 approximately, for ordinary liquids.

Similarly, vapour pressure is given by

$$P = Ae^{-Ml/RT}$$

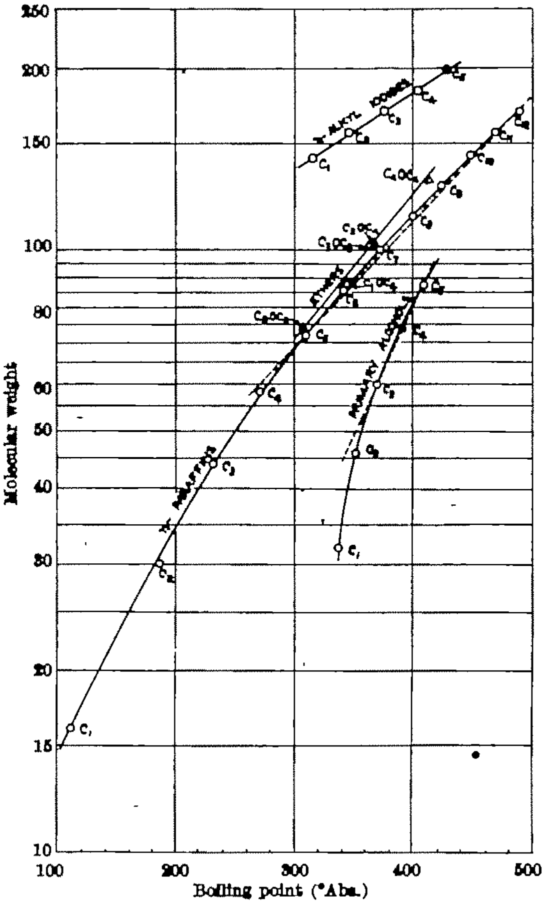
and the Clausius–Clapyron rendering of this formula is

$$\log\left(\frac{P_1}{760}\right) = -\frac{Ml}{2\cdot 3\,R}\left[\frac{1}{T_1} - \frac{1}{T_B}\right];$$

where the suffix B denotes boiling point.

$$\text{Thus}\quad \log\left(\frac{P_1}{760}\right) = -\frac{Ml}{2\cdot 3RT_B}\left(\frac{T_B}{T_1} - 1\right) = -K\left(\frac{T_B}{T_1} - 1\right),$$

since $\frac{Ml}{T_B}$ = constant from Trouton's rule.



It follows then that

$$\log \frac{\eta_1}{\eta_B} = K'\left(\frac{T_B}{T_1} - 1\right).$$

This last formula means that if $\log \eta$ is plotted against values of T_B/T for an homologous series like the normal paraffins, only one line is obtained. Such a graph was published in the literature recently[2].

Hence

$$\log \eta = K'T_B + K''$$

for an homologous series if a standard temperature, say 20° C., is chosen for T_1.

The accompanying graph shows that $\log M$ plotted against T_B for normal paraffins yields a curve: but if the portion appropriate to the liquids n–C_6H_{14} up to n–$C_{12}H_{26}$ be taken, a straight line would roughly pass through it. Thus, with approximation and limiting the carbon atoms to those mentioned,

$$T_B = A \log M + B.$$

$$\text{Hence}\ \log \eta = A'\log M + B',$$

which is Dunstan's law in a more exact form.

It is clear, then, that this law is limited by the following considerations:

(1) It can only apply to those homologous series which yield a solitary curve for log η *vs* T_B/T for all their members. Since first members in homologous series generally do not lie on these curves—for reasons which will be detailed in a later publication—it will not apply to first members of homologous series.

(2) The law can only apply to those homologous series which will yield approximately straight lines for log M *vs* T_B. Again, it is seen that first members will be excepted.

(3) When the effects of a certain radicle, say CH_2, are studied in different series, say alkyl iodides, *n*-paraffins and alcohols, the increment in log η due to CH_2 will be the same only for those series which have parallel straight lines for log M *vs.* T_B. Thus the iodides have been found to possess smaller values for the increment in log η due to CH_2 than the *n*-paraffins, whilst the alcohols possess greater values, and the ethers have identical values.

(4) The law is approximate only, even for *n*-paraffins.

Points from Foregoing Letters

D. Y. Solandt and C. H. Best, from experiments made with rats, conclude that deficient vagus function may be associated with a diet poor in choline and that this may, in part at least, be rectified by injected choline. Thus, it is suggested that choline deficiency may result in deficient formation of acetylcholine at the nerve endings.

A. S. McFarlane and M. G. Macfarlane report the presence in vaccinia virus of two types of lipoid, and of nucleic acid. The behaviour of the virus to mechanical treatment, to lipoid solvents, and to the action of sodium carbonate suggests that forces are present which are able to preserve the form of the particles in the absence of any demonstrable cell membrane.

F. L. Hopwood, M. H. Salaman and A. S. McFarlane find that dried vaccinial elementary bodies which have been extracted with benzene may be completely redispersed by means of ultrasonic vibrations. The virus particles so obtained have lost none of their original infectivity.

L. Halberstaedter finds that the hamster reacts to the subcutaneous injection of benzpyrene by tumour formation like the rat and mouse. Apart from a shorter incubation period, there are no peculiar features in the formation of the primary tumours. Passaging of a benzpyrene tumour in hamsters resulted in a remarkably high percentage of animals developing metastases, which were always localized in the lymph glands. This property is regarded as a peculiarity of this strain.

Unfertilized eggs of a sea-urchin have been inseminated immediately after irradiation with alpha-rays from radium C′ by M. Miwa, H. Yamashita and K. Mori. They find that the start of cleavage is delayed in some eggs, and with increasing doses of irradiation the number of eggs showing normal cleavage decreases; in some eggs cleavage stops altogether and disintegration occurs.

B. W. Doak finds that treatment of rhododendron cuttings which had already received a root-forming hormone with a mixture of certain amino-acids promotes root formation, thus substantiating a prediction by Went *et al.* that rooting of some cuttings is limited by lack of amino-acids.

Elizabeth S. Semmens states that the selective effect of polarized radiation in the hydrolysis of starch, both in the starch grain *in vitro* and in the living plant, is confirmed by a similar action on films of boiled starch, thus showing the effect to be a physico-chemical one. That the result is mainly due to the infra-red portion of the spectrum is demonstrated by the use of heated platinum gauze as a source.

H. L. Eastlick reports that reciprocal transplants of limb primordia have been made between 2½ and 3½ day duck and chicken, turkey and chicken, guinea and chicken, and turkey and guinea embryos. The transplants grew attached to the body wall or to the coelom of the hosts and the limbs thus obtained are normal in appearance. The flank grafts seem to be innervated. Several chicks bearing duck and guinea limbs have hatched and in at least one instance the additional leg is increasing in size.

R. W. Wood states that the scintillations given out by the 'lantern' of a fire-fly bitten by a spider when observed under low magnification have a similar appearance to a zinc sulphide screen under alpha particle bombardment. Study of the origins o scintillations in relation to the position of the bite might give information about the nervous system o the fly.

F. Lipmann puts forward a scheme for the de hydrogenation of pyruvic acid by *Bacterium Delbrücki* which involves the formation of acetylphosphate a an intermediate stage.

The absorption curve in the region 30 μ for tetra chlorethylene dissolved in paraffin is submitted b J. Duchesne and M. Parodi. The frequencies of the two absorption bands observed are in agreement with the predictions of a theoretical discussion of th vibration spectrum of this substance.

S. K. Mukerji and L. Singh have investigated the Raman spectrum of solid *p*-diphenylbenzene, an deduce that the molecule is planar.

Dunstan's law for the relationship of viscosity with the molecular weight of members of an homo logous series is derived by applying Trouton's rule to the Clausius-Clapyron and Andrade equations The limitations of the law become apparent from this derivation and it is shown by A. H. Nissan tha the equation log. $\eta = K'T_B + K''$ is the fundamenta one giving rise to Dunstan's log $\eta = aM + b$ onl in certain cases.

RESEARCH ITEMS

New South African Stone Age Cultures

DR. E. G. N. VAN HOEPEN in his presidential address to Section E of the South African Association for the Advancement of Science on July 5, 1938 *Argeologiese Navorsing Nas. Mus.*; 9, 10, 1939), in discussing certain aspects of South African archæology, adduced argument for the conclusion that there had been in the Stone Age in South Africa, as in Europe, two civilizations, existing side by side simultaneously, of which one was characterized by implements made on cores ('Fauresmith', Vaal, Stellenbosch), and one by implements made of flakes (Koning, including three industries, Wilton, Smithfield, Koning; Mossel Bay; and Pniel). Further research and exploration have since brought to light new cultures, confirming and extending the application of this view. A number of cleavers from Wellington made from river boulders, one side showing the original surface, are of more primitive form than the Vaal cleavers, and though Pniel in shape and technique, represent an earlier flake industry, which it is proposed to call the Wellington industry, to distinguish it from the Pniel industry, in conjunction with which t constitutes the Pniel culture. It is contemporary with Stellenbosch. A second new culture comes from the Brakfontein farm, and is a congeries of lakes and implements which cannot be placed in any of the known industries. The flakes are large, a breadth of twelve inches being not uncommon. More often the implements are broader than they are long. Flakes have been made into implements by secondary rimming of the edge opposite the bulb of percussion. They resemble flaying knives from the Koning industry, but are larger and cruder. Probably Koning is derived from them. Two other localities are known but not yet worked. The Brakfontein culture, as it is proposed to call it, may have been contemporary with earlier Mossel Bay, to which belong a number of long flakes recently found at Swartfontein with 175 hand-axes of the Vaal and Stellenbosch cultures. The Swartfontein flakes are distinct from the Mazelspoort, and it is proposed to differentiate the two as the Swartfontein and Mazelspoort industries, constituting together the Mossel Bay culture.

Chromosomes of the Pig

F. A. E. Crew and P. C. Koller (*Proc. Roy. Soc. Edin.*, 59, 163–175; 1939) show that the chromosome complement of the pig is $2n = 38$, with a range n chromosome size of $7 \cdot 5\,\mu$–$1 \cdot 5\,\mu$. There is little, f any, terminalization between mid-diplotene and metaphase, and the chiasma frequency in some hromosomes appears to be proportional to the ngth of the chromosome. The five larger bivalents xhibit localization of chiasmata; consequently, ecombination of genes on these chromosomes is xpected to be peculiar and limited. The Y, with sub-terminal centromere, pairs with one arm of he medianly attached X, while the other arm of he X chromosome appears to be the differential egment. Pre-reduction is obligatory in the XY bivalent. Evidence of at least one inversion is iven.

Chromosome Rearrangements in Drosophila

B. P. KAUFMANN (*J. Hered.*, 30, 171–190; 1939) irradiated Drosophila males and studied the salivary gland chromosomes of the progeny. Deficiencies, duplications, translocations, transpositions (intrachromosomal translocations) and multiple exchanges involving up to eight breaks were found. The author points out that chromatid and chromosome breaks caused by X-rays do not provide unequivocal evidence for the time of chromosome splitting.

Temperature Rhythm in an Ant-hill

THE temperature changes within the mound of a widely distributed species of Japanese ant, *Formica truncorum truncorum* var. *yessensis*, have been investigated by Mutsuo Katô (*Sci. Rep. Tôhoku Imp. Univ.*, 4 Ser., 14, 53; 1939). The diurnal temperature rhythm in the interior of the mound was remarkably different from that of the air temperature, for at a depth of 20 cm. or more below the surface it was almost constant, ranging only from 26·1° to 28·8° C. Even at a depth of 10 cm. the temperature was fairly constant (24·6°–30·9° C.), but at lesser depths the influence of the rhythm of solar radiant energy became more and more apparent as the surface was approached. The mounds are composed of masses of withered grass, bits of leaf-stalks and twigs loosely piled on bases of living trees or stumps; they are thus partially insulated by the content of air interlaced in the material of the mound. Nevertheless artificial mounds showed, at corresponding depths, greater temperature fluctuations than the ant-hills, and this was due to temperature regulation within the latter. The main source of heat is undoubtedly the sun, and although during periods of activity the ants may add a little to the sum total, further regulation of the internal temperature is brought about by the opening and closing of the entrances to the mound. When the day is declining many ants carry material which is used in blocking the passages made for exit during the day-time, and thus the loss of heat which would take place during the night is reduced.

Market Economics of the Apple

AN interesting study of the complex relations between quality and price of McIntosh apples sold in the New York City markets has been made by John R. Raeburn (*Cornell Univ. Agr. Exp. Sta. Mem.* No. 220. Ithaca, U.S.A., March 1939). The average diameter, the amount of red-coloured skin, the practice of 'facing' or having the top layer of apples superior to the general sample, and serious and not-serious defects produced by insect attack, by fungal parasites or by bruising, all affect the price received. Their effects are interrelated, and a method of surface correlation involving the presentation of data in three dimensions has been used to reveal the joint effects of two variables upon the dependent variable, price. One important result of the study concerns the economic effects of high-quality grading. Separation of the highest quality fruit does not produce the greatest financial return; the utilitarian needs of the ultimate consumer provide a surer basis for grading. Prices recorded in the present investigation indicate the gastronomic, rather than the æsthetic, value of the fruit. Serious and not-serious defects affect prices jointly, for the influence of one type depends upon the proportion of the other. This finding vindicates the numerous recent studies of pests or parasites which have little effect upon their hosts. They predispose the market against even slight occurrences of more serious defects. The paper under review gives many other detailed correlations, several of which are crystallized into definite recommendations for the farmer or the market organizer.

Observation of Growing Roots

OBSERVATION trenches for the examination of roots in the field are described by W. S. Rogers (*J. Pom.*, 17, 99; 1939) in an account of four years' work on the growth of apple roots at East Malling. The trenches, which were 4 ft. 6 in. deep and 2 ft. 6 in. from the tree trunks, were provided with plate-glass windows held against the soil profile. They were enclosed to form wooden cabins and protected from light. 14 year-old Lane's Prince Albert apple trees were observed over four years and the time and rate of root growth, suberization and formation of laterals recorded. During active growth, the rate of root elongation approximated 3 mm. per day, while suberization occurred when the roots were a week to a month old. Small roots died and disappeared after suberization. Larger ones persisted, often with rapid secondary thickening, and produced laterals. Root growth was closely correlated with soil temperature, very little growth occurring in winter at soil temperatures from 35° F. to 45° F. Active growth began at about 45° F. and increased up to 69° F. (at 8 in. deep). It began before the leaves unfolded, and continued after shoot growth ceased. A fall in soil moisture checked root growth though the moisture content was still well above the wilting range. In spring, most root growth occurred in the warmer surface layers of soil and in winter in the lower layers. The greatest concentration of roots occurred at a depth between 5 and 30 inches. A comparison of trees on stocks I, IX and XVI showed that the amounts of root corresponded with the relative vigour of the stocks, but the mean growth-rate per root was similar for all stocks. It appeared that physiological differences between the rootstocks were relatively small.

Apparent Shape of Protein Molecules

IT has been recognized for some time that protein molecules are probably not spherical and the term dissymmetry constant was introduced by Svedberg for the ratio f/f_0, where f and f_0 are the measured molar frictional coefficient (derived from sedimentation and diffusion experiments) and the theoretical value for a spherical molecule of the same molecular weight, respectively. H. Neurath, (*J. Amer. Chem. Soc.*, 61, 1841) has applied Perrin's diffusion equation to the problem, this equation involving the long and short axes of a prolate ellipsoid of revolution. The results are subject to large limits of error but they show that, with a few exceptions, protein molecules are not spherical, and most exhibit high molecular dissymmetry. Proteins which belong to different groups as regards their molecular weight become members of the same group if arranged according to their molecular dimensions. Thus, cytochrome C, gliadin and erythrocruorin, with molecular weights of 15,600, 26,000 and 31,400, have a common short diameter of about 18 A. Comparison of the dimensions of proteins with those of their respective dissociation and aggregation products indicates that cleavage occurs only in directions parallel to either the major or minor molecular axis.

Diffusion Velocity and Molecular Weight

CONSIDERABLE interest has recently been shown in the use of diffusion velocity in determining molecular weights, calculations having usually been made by the Stokes-Einstein diffusion equation $D = (RT/N) . 1/(6\pi\eta r)$. L. Friedman and P. G Carpenter (*J. Amer. Chem. Soc.*, 61, 1745; 1939) point out that the diffusion coefficient to be used in this equation should be that at infinite dilution and by plotting diffusion coefficients against the square root of the concentration and extrapolating the straight line to zero concentration for some sugars and salicin, they find reasonable values of the molecular weights. An experimental study of the diffusion velocity of glucose by this method gave the correct molecular weight. It is pointed out that the relationship holds for a substance of molecular weight as low as 180, whereas most investigators have felt that the Stokes-Einstein relation could not be applied to substances of such low molecular weight.

Detection of Carbon Disulphide Vapour

LEAFLET No. 6 of the series by the Department of Scientific and Industrial Research on methods for the detection of toxic gases in industry deals with carbon disulphide vapour (H.M. Stationery Office 3*d*. net). It is stated that the permissible concentration of carbon disulphide vapour in the atmosphere of work-rooms should be kept well below one part in 30,000 of air and preferably below one part in 100,000 The method of detection of the vapour depends on its interaction with diphenylamine and copper acetate to produce a coloured compound, copper diethyldithiocarbamate, and full instructions for carrying out the tests are contained in the leaflet which is bound in strong paper covers.

Impurities in Brass

FOR the last seven or eight years, on the recommendation of the American Society for Testing Materials, the Non-Ferrous Ingot Metal Institute ha supported a research on the effects of impurities and heat treatment on the physical properties of bras which has been carried out by H. B. Gardner and C. M. Saeger at the National Bureau of Standards Two papers on the effects of pouring temperatur and of sulphur and iron impurities have already been published, and in the June issue of the *Journal o Research* of the Bureau a third on the effects o aluminium and of antimony appears. Cast red bras of composition 85 per cent copper, 5 per cent each tin, zinc and lead was remelted and up to 0·10 pe cent aluminium or 0·23 per cent antimony added and specimen bars cast at temperatures from 1230° to 1065° C. in chilled or unchilled or sand moulds The running properties were observed and tests o density, hardness, tensile strength, porosity unde hydraulic pressure and electrical conductivity wer made. Pouring temperature had little effect, but aluminium, while improving the running properties lowered the ductility, hardness, tensile strength and electrical conductivity and raised the porosity of th brass. Antimony increased slightly the running and decreased slightly the conductivity, but its oth effects were insignificant.

THE DUNDEE MEETING OF THE BRITISH ASSOCIATION

GENERAL ARRANGEMENTS

PREPARATIONS for the Dundee Meeting of the British Association, which will open on August 30, are in their final stage. There are indications that fear for the international situation is keeping a few visiting members away, but powerful efforts are being made in Dundee to secure the support of a strong body of local members such as is always anticipated at a Scottish meeting.

The main outlines of the programme have been announced long ago, and the activities of the sections are given under their own headings, but there are certain new features to be mentioned here. The evening lecture on "Science and Social Pioneering", which Dr. Isaiah Bowman, president of Johns Hopkins University, will deliver, will be the first of a new series furnishing outward evidence of the intimate relations between the British and American Associations, which were so happily strengthened during the meeting at Cambridge last year. This series will be known as the British and American Association Lectures, a title which, if something cumbrous, has at least the merit of self-explanation. A British lecturer will be heard at an American Association meeting next year, and so thereafter, in alternate years at future meetings of the two Associations, this invaluable contact is intended to be maintained.

The new Division for the Social and International Relations of Science, created by the General Committee of the Association last year, seems already to have established itself firmly. In case it should be feared that its potential field is beyond the scope of the Association's work, it may be said at once that there is no evidence of this: the outlook of the Association (taken as a whole) is wide, and its mechanism elastic, and the new Division is in direct line of descent from the intentions of those who founded the Association more than a century ago. It will be evident from the transactions of the Division at Dundee that through it the Association is establishing contacts with other organizations which otherwise might have been neglected. The Division will hold three sessions, at which there are to be discussed an interim report on an inquiry into the organization of research in Britain, in which the Division is associated with P E P (Political and Economic Planning); population problems; international intellectual co-operation, introduced by Prof. Gilbert Murray; and nutrition, introduced by Sir John Orr. The Division has also arranged the Sunday evening lecture requested by the local executive in Dundee, which will be given by Sir Richard Gregory as chairman, on "Contacts of Religion and Science"; the public as well as members of the Association being admitted.

A third unusual feature in the programme of the meeting, though not without precedent, is found in the two special sessions dealing with jute, the material (it need scarcely be said) of one of Dundee's staple industries. Every scientific aspect of this material and the industry associated with it will be dealt with by experts, and the Textile Institute will collaborate in publishing the results.

The familiar programme and daily time-table will appear in a new guise. Its pages are increased to correspond in width (though not in depth) with those of the forthcoming quarterly form in which the annual report will be published in future. Moreover, the *Journal* of sectional transactions, containing abstracts of papers, will appear within the same covers and not as a separate publication, an arrangement, carried out not without heart-searching on the part of the administration, which should make for the general convenience. The new quarterly, of which the first number will appear at the end of October, will bear the title of *The Advancement of Science*, a name hitherto attached to the collection of presidential addresses which has appeared for some years at the time of the meeting. This collection will now be discontinued, but in its place separates of the various addresses will be on sale at the meeting.

Entertainments detailed in the programme, while nowise overwhelming it, fully exemplify Scottish hospitality, notably the generous number of garden parties to be given by private hosts. The Corporation and the University College both entertain, as is customary, as also do the Dundee Harbour Trustees with a river trip. The Eastern Club, the University College Students' Union, the Dundee Rotary Club, the Dundee Medical Club and the Forfarshire Medical Association, the Overseas League, and, it scarcely need be added, several famous golf clubs, including the Royal and Ancient of St. Andrews, all offer hospitality in various forms. Finally, masonic members of the Association will find very special interest in a meeting arranged for them by the Dundee St. Mary Lodge, to exemplify a working of the Scottish Constitution.

The reports of the Council, the Down House Committee, and the Division for the Social and International Relations of Science, which will be presented to the General Committee, cover a range of incidental interests from the safeguarding of native tribes in Australia to that of the green belt around London, and from the possibility of a future annual meeting in Brighton to that of scientific delegations to the West Indies and Southern Rhodesia. It is no matter for wonder that the general treasurer in a recent appeal, and again in his forthcoming report, has asked for extended support for the Association by way of membership "from all those who appreciate the benefits that science confers and wish to aid the Association in discharging its function of the advancement of science".

SECTIONAL PROGRAMMES

SECTION A (MATHEMATICAL AND PHYSICAL SCIENCES)

SECTION A (Mathematical and Physical Sciences) has for many years had two sub-sections, one for mathematics and the other for cosmic physics, and each of them this year has some interesting discussions to offer. On the Saturday, there will be a discussion on "The Teaching of Mechanics", opened by Prof. E. A. Milne and continued by speakers representing Scottish and English schools and universities. Although the meeting is not a joint one, it is hoped that the choice of day will permit some members of Section L to attend and to take part in the open discussion. In cosmic physics, a discussion on solar-terrestrial relationships, to be opened by Prof. E. V. Appleton, promises much of interest, as also does one on the surface temperatures of stars.

It is not to be thought that the only matters of interest are those pertaining to the special interests of the subsections (though these are not so specialized as to be unintelligible to the ordinary member), for the main section shows a judicious blend of 'new' and 'classical' (or 'applied') physics, which should interest many. Starting on Thursday with electron optics and the presidential address by Mr. R. S. Whipple on "Instruments in Science and Industry", the former of which is 'electronic physics' but of wide everyday application, the section proceeds on Friday to artificial radioactivity, and on Monday to the theoretical but applied subject of "High-Speed Flight", and thence on Tuesday to high temperature physics, the programme of which is largely devoted to papers from the National Physical Laboratory and from laboratories of the steel-making industry. In the course of this session, a coloured film will be shown to illustrate some of the physical problems of modern steel making.

Section B (Chemistry)

THE proceedings of Section B will begin with the presidential address by Prof. E. K. Rideal on "Film Reactions as a New Approach to Biology", and the rest of the day will be devoted to a joint discussion with Section I on "Tissue Respiration", to be opened by Prof. R. A. Peters. Dr. Malcolm Dixon will deal with catalysis in tissue respiration (catatorulin) and Dr. H. Theorell (Stockholm) with the flavoproteins. After an account of cytochrome and similar compounds by Prof. D. Keilin, Dr. F. Dickens will consider the interpretation of intermediary metabolism from measurement of tissue respiration, and Dr. J. H. Quastel that of narcosis. Dr. S. Ochoa will deal with carbon dioxide evolution and cocarboxylase. Prof. H. S. Raper will discuss the control of tissue respiration, and other aspects of the subject will be presented in discussion by Dr. D. E. Green, Sir F. Gowland Hopkins, Dr. H. A. Krebs, Dr. T. Mann and Dr. E. P. Poulton.

A discussion on "Light Alloys" will be opened by Dr. C. H. Desch, who will speak of their growing importance and will refer in particular to their mechanical strength and to their resistance to corrosion. Dr. A. G. C. Gwyer will discuss the constitution of aluminium alloys and Mr. W. C. Devereux will describe the controls of production of light alloys, including spectrographic analysis and the X-ray control of their thermal and mechanical treatment. Their industrial uses will be dealt with by Prof. A. von Zeerleder. An exhibition illustrating the uses of light metals and alloys, with a research section, will be open throughout the meeting.

Progress in physical chemistry is largely dependent on the development of new technique. Not only does such technique help to solve specific problems unassailable by the older methods, but it also opens up entirely new lines of investigation. This topic will form the subject of a discussion in which new methods and their bearing on problems connected with the mechanism of chemical reactions will be described. Radioactive and non-radioactive indicators ('labelled atoms') will be dealt with by Prof. S. Sugden and Prof. W. F. K. Wynne-Jones respectively. Dr. M. Ritchie will discuss reactions of free atoms; Prof. T. Alty accommodation coefficients, and Dr. H. W. Melville will describe recent technique in photochemistry.

At the last Dundee meeting of the British Association in 1912 Prof. A. McKenzie opened a discussion on the migration of groups and dealt especially with the Walden rearrangement. During the quarter of a century which has elapsed, the Dundee school under his leadership has greatly advanced our knowledge in this field. On the present occasion, Prof. McKenzie and Dr. R. Roger will open a discussion on intramolecular change involving the migration of groups, and will give an account of their work on deamination and dehydration involving semi-pinacolinic rearrangements in which optically active alcohols and glycols have been used. Contributions will also be made by Prof. M. Tiffeneau (Paris), Dr. S. F. Birch, who will deal with the catalytic isomerization of paraffins, Dr. A. K. Mills and Dr. T. S. Stevens.

A special feature of the meeting will be a two-day discussion on jute, the principal industry of Dundee, including chemical and physical as well as economic aspects of the subject. In this connexion a comprehensive exhibition will be open throughout the meeting. Two popular lectures will be given. Dr. D. A. Spencer will deal with colour photography and Dr. H. W. Melville will give an experimental lecture on the methods of producing light.

By kind invitation of the University Court, a visit will be made to the University of St. Andrews, and visits to jute-spinning mills and Messrs. Moncrieff's glass works at Perth are being arranged. The usual sectional dinner will be held. The following chemists have accepted the Council's invitation to attend as foreign guests of the Association: Dr. H. Theorell (Stockholm), Prof. Marc Tiffeneau (Paris) and Prof. A. von Zeerleder (Zurich).

Section C (Geology)

THE programme of Section C (Geology) will, for the most part, be devoted to Scottish geology. Prof. H. H. Read has taken as the title of his presidential address "Metamorphism and Igneous Action". He has spent much time in the study of this subject in the Highlands and elsewhere, and this summary of his views will be awaited with interest.

Discussions are to be held on the raised beaches of the Forth and Tay and on the boundary between the Carboniferous and the Old Red Sandstone. These are matters of considerable importance to geologists working in Scotland, and the contributors are largely drawn from the Scottish branch of the Geological Survey.

A number of short individual papers will be presented. These will include: Prof. Innes on the geology of the Dundee district; Dr. J. Pringle on the discovery of Cambrian fossils in the Highland Border Series, an important advance in the study of these rather problematical rocks; Dr. M. Macgregor on the buried channel of the Forth, with Dr. Pringle on the Carboniferous rocks of Bridge of Awe and with Prof. J. Ritchie on remains of reindeer from the glacial deposits of Glasgow; Dr. T. S. Westoll on the fish fauna of the 'Caledonian' Old Red Sandstone; Prof. W. T. Gordon on a new type of seed from the Carboniferous rocks of Tantallon; Dr. E. Dix on the Coal Measures of Warwickshire and with Mr. W. D. Ware, on those of Pembrokeshire;

Dr. A. Lamont on antidunes in geology; Mr. E. H. Davison on the solubility of rocks and Mr. F. W. Anderson on algal limestones in east Fife and on ostracod zones in the Wealden and Purbeck Beds.

SECTION D (ZOOLOGY)

PROF. J. RITCHIE'S presidential address to Section D is entitled "Perspectives in Evolution".

Two discussions have been arranged by the Section. The first of these will cover various aspects of parthenogenesis. Prof. A. Vandel, the distinguished French authority on this subject, will open the discussion, Prof. Peacock will give a review of recent researches in experimental parthenogenesis, and Dr. Sanderson and Miss Malcolm (two workers from Prof. Peacock's laboratory) will contribute papers on the cytological aspects of parthenogenesis in snails and sawflies.

The second discussion will deal with the biology of salmon and trout, and, in the six papers arranged under this heading, a résumé of our present knowledge of the migratory habits, homing instinct, food and sexual phases of these fishes will be given. Mr. Menzies, of the Scotch Fishery Board, will open the session, and other speakers include Prof. Orton, Mr. R. M. Neill and Mr. MacFarlane. Mr. D. F. Leney will contribute an account of modern hatchery methods for salmon and trout.

Dr. Fraser Darling will give a semi-popular lecture on the grey seal in which will be included a summary of his recent researches on the behaviour and habits of the colony of seals on North Rona. Prof. Brambell and Mr. H. A. Cole will describe a new ciliary organ found in enteropneusts which suggests affinities with the hypophysis of higher vertebrates and adds further evidence for the chordate affinities of the Hemichorda. Dr. Worthington will outline the developments in research on fresh waters which have been inaugurated at the Freshwater Biological Station at Wray Castle.

There is to be an exhibition of biological films produced by the Strand Film Zoological Production, Ltd., Gaumont British Instructional Films, Ltd., and Associated British Film Distribution, Ltd. Sectional excursions have been arranged to Glen Doll, the Field Station of the Department of Natural History at University College, Dundee, to the Perth Museum, and to the Silver Fox Farm of Mr. J. B. A. Mackenzie at Balbeggie.

SECTION E (GEOGRAPHY)

SECTION E (Geography) at Dundee will this year depart from precedent in that it will not open its meetings with the presidential address. Instead he first morning will be given to certain urban studies of Scotland and to a joint discussion with many other sections on the proposed National Atlas. This latter proposal came before the Section at Cambridge and received general support. Since then a representative committee has been at work on the scheme, and its report will form the basis of the discussion. In the afternoon there will be two papers dealing with recent developments in the Ordnance urvey.

On Friday Mr. A. Stevens will deliver his presidential ddress, there will be one paper by Mr. Linton suggesting a new idea in the evolution of some of the Scottish rivers, and the local secretary, Dr. J. F. Scott, will give a preliminary account of the sectional excursions.

The excursions begin on Friday afternoon with a visit to the city of Dundee and to the Hillbank Linen Works. On the following day the Section will make a circular tour of the Fife peninsula, and on Sunday a visit will be made to part of the Highlands. Another excursion, on Tuesday, will give opportunity to study the agricultural geography of the Carse of Gowrie.

On Monday all papers deal with topics or regions which are outside Great Britain. Prof. T. M. Knox will raise some important points concerning the future of the palm oil industry in West Africa. Dr. N. Friberg, a foreign guest of the Association, will describe highway developments in Sweden. The Spanish zone in Morocco, the great basin of North America, and current movements of population in Eire are the subjects of the remaining papers.

On Tuesday, apart from one paper on the geography of Cheshire at the time of the Domesday Survey, the general topics are more closely related to Dundee or its neighbourhood. Thus one paper deals with population changes in the Lower Tay valley since 1755, and another discusses the geographical background of Scottish sea-borne trade in the eighteenth century. Dr. Snodgrass, whose studies of the agricultural geography of Scotland are well-known, will make comparisons of population density and agricultural type in Britain and the Continent.

The meetings of the Section will end on Wednesday morning with two papers on subjects of physical geography, in one of which Mr. W. V. Lewis will further develop his views on plucking as a factor in glacial valley erosion.

The programme of the Section covers a wide field, and apart from its general interest affords many indications of the way in which geography plays a part in current problems. It is hoped that this side of the Section's activities will make an appeal to those members of the Association who will be naturally interested in the new Division for Social and International Relations of Science.

SECTION F (ECONOMICS)

BY the nature of its subject, the work of Section F (Economics) is essentially concerned with public welfare. It is current events which largely decide the aspects to be discussed. Last year unemployment and the trade cycle occupied the first place. For the Dundee meeting, a number of the papers concern urgent Scottish problems. There are to be papers on housing in Scotland, on the finance of Scottish Local Government, on the finance of new enterprises in Scotland, and on the economy of the crofting districts. Lord Douglas Hamilton will open a special afternoon session on the problem of the distressed areas, and the various measures taken to assist them.

Although the name of Dundee has always been associated with the jute industry, it has been the home of some financial activities of more than local importance. There will be a paper on the Dundee Investment Trusts. Three problems of 'planning' will come up for discussion—the localization of industry, the economics of urban decentralization, and the consequences of the legislation concerning the coal-mining industry. In contrast to these detailed topics, a whole morning will be given up to the discussion of the theory and problems of socialism, in its national and international aspects. It is perhaps a significant sign of the times that the Presidential address by Prof. H. O. Meredith will be on Rates and Taxes.

SECTION G (ENGINEERING)

THE presidential address to the Engineering Section will be delivered by Mr. H. E. Wimperis, who was for many years director of scientific research at the Air Ministry, and has recently been in Australia and New Zealand to advise those Governments upon the establishment of aeronautical research organizations. The subject of his address will be the "Future of Flying". Another item of great aeronautical interest will be a paper to be read by Major R. H. Mayo describing his composite aircraft which is under trial by the Air Ministry and Imperial Airways. The paper will be followed by a discussion which will be opened by a representative of Messrs. Shorts, who have built the trans-Atlantic flying boats, and a representative of Sir Alan Cobham, who has developed a system of flight refuelling.

The Section has during several years given careful consideration to the training of engineers, particularly in university courses. The matter was dealt with last year by Prof. R. V. Southwell in his presidential address and afterwards a questionnaire was circulated to a large number of practising engineers and firms who employ university graduates. A very large number of answers have been received, and these will be shortly reviewed by Prof. Willis Jackson who has been mainly responsible for the work.

An important paper will be read by Prof. R. G. H. Clements on the design of roads. There will be a number of other papers, and the Section will repeat its experiment of last year by including five short papers by junior engineers, each of whom will be allowed thirty minutes for his paper and the discussion which will follow it.

SECTION H (ANTHROPOLOGY)

ACCORDING to custom, the programme has been arranged so that the various branches of the study of man are fairly represented. The section has this year restricted the number of papers to be read, in order that there may be adequate time for discussion. Prof. W. E. Le Gros Clark will give the presidential address (Friday) on "The Scope and Limitations of Physical Anthropology". The Monday morning is devoted to a joint discussion with Section I (Physiology) on "Nutrition and Physique", which should appeal to a wide public. In the afternoon of the same day important communications will be read on "The Affinities of the South African Pleistocene Anthropoids" (Dr. R. Broom) and on "Recent Discoveries bearing on Human History in South Africa" (Prof. Raymond Dart). Dr. Broom has sent a collection of casts which will be exhibited at the meetings. Two papers of philosophical interest will occupy the latter part of the afternoon: "The Evolution of the Human Brain" (Dr. S. Zuckerman) and "Mental Evolution of the Primates" (Dr. R. H. Thouless).

In the periods given to archæology there will be papers on a recent discovery of cult objects at Grimes Graves (Mr. A. L. Armstrong), an Irish hill-site of the Megalithic Period (Dr. E. E. Evans), the types and chronology of beakers in Spain (Dr. Bosch Gimpera), connexions between the Lake District and Ireland in the Bronze Age (Miss C. Fell), and on the prehistory of Uganda (Prof. C. van Riet Low and Mr. E. J. Wayland). Having special reference to Scotland there will be two papers: "Prospects of the Advancement of Knowledge in Early Scottish History" (Dr. A. O. Anderson), and "Some Recent Work of the Royal Commission on Ancient Monuments (Scotland)" (Mr. Angus Graham).

General ethnology is represented by communications dealing with a wooden tea-pot from Tibet (Mr. R. Kerr), racial crossing and cultural efflorescence (Prof. J. Murphy), the crane dance (Prof. P. E. Newberry), sign language and the education of dea mutes (Sir Richard Paget), spiritual journeys o the seer (Mrs. N. K. Chadwick), change of persona name among the Biblical Hebrews (Prof. A. M Honeyman), primitive cults in the religion of the Old Testament (Prof. E. O. James), the wares of a Moroccan native doctor (Mr. W. Fogg). A joint discussion with Section L (Education) on anthropology in education has also been arranged.

In the section dealing with the ethnology of the British Isles there are papers on ballads and tune which travel (Prof. W. J. Entwhistle), the folklor of death cairns (Miss Maire McNeill), the folklor associated with fishing in the north-east of Scotlan (Mrs. M. McCleod Banks), the human interest of a highland folk-collection (Miss I. F. Grant), and with a survey of some Scottish folklore and its origin (Rev. Canon J. A. McCulloch). Mrs. Catrion MacKintosh will discuss Hebridean folk-songs, an will sing some of the songs to the accompaniment o the old harp.

SECTION I (PHYSIOLOGY)

ALTHOUGH the Physiological and Biochemica Societies each meets nine times every year yet Section I (Physiology) of the British Associatio offers certain facilities to physiologists and to biochemists rarely provided by their own societie These facilities are prearranged discussions o various topics, contact and joint discussion wit members of other sections and the opportunity t give publicity to authoritative views on scientifi matters of public interest. This is well exemplifie by the programme of Section I for the Dundee meeting.

On the Thursday morning, Sections B and I wil both hear Prof. E. K. Rideal give his presidentia address to Section B on the importance of surfac film phenomena in biology. Thereafter, there wil be a joint discussion with Section B for the rest o the day on "Tissue Respiration". The subject wil be introduced by Prof. R. A. Peters, who convene the discussion. Nine papers will be given. A featur will be the allocation of time for informal discussio of the subject by recognized authorities who hav promised to attend.

On Friday morning, Section I will discuss "Th Problem of Pain". Very appropriately they wi visit St. Andrews for this purpose, where the memor of Sir James Mackenzie, in his day the outstandin authority on the subject, is still fresh in the min of local workers. In the afternoon there will be visit to the Mackenzie Institute for Clinical Researc and to places of scientific and historical interest the neighbourhood.

On Monday morning there will be a discussion o "Nutrition and Physique" with Section H (Anthr pology). Here it is to be expected that the vexe question of "Nature versus Nurture" will recei much attention.

On the Tuesday morning Prof. D. Burns w deliver his presidential address to Section I. H subject is "The Assessment of Physical Fitness His communication will be followed by a discussi n the same topic which will extend into the afteroon.

Both the discussions on the Monday and the Tuesay deal with matters of great importance at the resent time. Their scientific interest is equalled nly by their practical significance for human welfare. t is to be hoped that many members of the Associaon, not primarily physiologists, will take the opportunity to be present at these two discussions.

SECTION J (PSYCHOLOGY)

THE presidential address by Mr. R. J. Bartlett is on measurement in psychology.

Two discussions have been arranged. One is on aining the mind. Starting with the old problem f formal training, possible ways of giving a broad nd general discipline will be debated. The other discussion has to do with the use of films in propaganda, ntertainment films and public taste, their influence n the child, and so on.

The remaining papers cover most of the fields of sychology. Of broad interest are papers on methodology in psychological medicine, the ego in his world, e primitive nature of poetic genius, and the sychology of frustration. Industrial problems dealt ith are the selection of skilled engineering workers, e sorting process in laundries, the analysis of skill y motion study, and the everyday work of a vocaonal adviser; while under mental testing and general xperimental psychology come papers on the psychological respectability of physical activity, common nse in music testing, the relations between characteristic interests of schoolboys, the predicting of sychological aptitude in students, experiments on e ultra-perceptive faculty, measures of reliability in oup intelligence tests and recent experiments in ocial psychology.

SECTION K (BOTANY) AND DEPARTMENT K* (FORESTRY)

THE president of Section K (Botany), Prof. D. Thoday, will deal in his presidential address with e "Interpretation of Plant Structure". Captain eorge I. Campbell, the chairman of K*, will speak n "Forestry in Scotland".

The semi-popular lecture, to be given by Sir Frank tockdale, will deal with "The Application of conomic Botany in the Tropics". Department K* as organized a special meeting on the larch, and a int meeting of Section K and Department K* will e concerned with local races of trees, seed proenance, and allied topics. The last Tuesday afteroon of the meeting will be given up to the demonration of exhibits, and the proceedings on that fternoon will finish with the showing of a film, Coloured Impressions of Tweeddale and the Borders" y Miss I. M. Hayward.

In addition to these special items, Section K and epartment K* will have before them a comprehensive programme ranging over many aspects of otany and forestry, including a number of communications from Scottish workers. The serious bours of the meeting rooms will be varied by cursions to places of interest to botanists and resters, the chief excursions taking place during e week-end.

SECTION L (EDUCATIONAL SCIENCE)

FOLLOWING customary practice in recent years the papers to be read before Section L (Educational Science) are grouped around one main theme with two subsidiary themes. The main subject at the Dundee Meetings will be "Education in and for Industry" which will be discussed on the mornings of Thursday, Friday and Monday. Papers will also be read on Monday on recent educational research in Scotland, while on Tuesday there will be a symposium on the Spens Report.

The President of the Section for 1939 is Dr. A. P. M. Fleming, director of research and training to Metropolitan Vickers Co., and it is fitting in view of the paramount importance that his firm attaches to research and training that his presidential address on Thursday will be on the subject of education for industry. Following the address, papers on aspects of the same theme will be read by Mr. Lester Smith, Dr. Fisher and Mr. Mouat Jones, who will respectively analyse the part played by local education authorities, public schools and universities in educating those who enter industry at various age-ranges and in various capacities. On Friday, papers will be read on education in industry by Mr. Longmuir of Messrs. Mavor and Coulson, and Mr. Darbyshire of the L.M.S., who will describe schemes of training carried out by industrial firms. The contribution made by technical colleges will be discussed by Mr. C. F. Richardson and Principal Smail of the Heriot-Watt College. Post-advanced courses at the universities will be described by Dr. Willis Jackson.

At Monday's meetings papers will be read on aspects of industrial education by Mr. Herbert and Dr. Radley who are the chief research officials at the L.M.S. and the G.P.O. respectively. Educational research in Scotland will be discussed by Prof. McClelland and Mr. Hepburn on the same day. Papers on the Spens Report will be read on Tuesday morning by Miss L. Grier, Mr. Henshall, and Mr. J. B. Frizell.

During the meetings the reports of two research committees will be presented (*a*) on the organization of educational research (Friday), (*b*) on the informative content of education (Monday). Visits will be paid on Monday to Perth Academy and on Tuesday to the Dundee Child Guidance Clinic.

SECTION M (AGRICULTURE)

THE whole of the programme of Section M (Agriculture) has been designed to be of immediate practical interest to the farmer, and in all of the discussions which have been arranged, a balance has been kept between recent scientific work and its application in practice. Sir Thomas Middleton will open the proceedings on Thursday with his address entitled "Practice with Science" which will be the keynote for all that follows. Other papers on that morning are "The Breeding and Feeding of Beef Cattle" by Mr. Howie, "Sprouted Fodder in Cattle Feeding" by Principal Paterson, and "Pre-digestion of Coarse Fodders" by Mr. Godden.

Friday morning will be devoted to a discussion on agricultural education to be opened by Mr. MacGregor, who will give an account of some Fife experiments in agricultural education. Mr. Wannop will deal with the organization and working of young farmers' clubs, and Prof. Comber will speak on advisory work in relation to agricultural education and research.

A subject of immediate practical application, namely, grass conservation, will be discussed on Monday morning. This will be opened by Mr. Martin Jones, who will deal with "The Place of Grassland in Modern Food Production". He will be followed by Dr. Watson, Mr. Roberts and Prof. Kerr, who will speak respectively on the scientific, economic and engineering aspects of grass conservation.

A subject suited to the locality is that of seed potato growing. A discussion on this will be opened by Mr. Wedderspoon, who will speak as a growe Virus diseases and seed potatoes will be considere by Dr. Cockerham, and Dr. McIntosh will de with the importance of variety in potato produ tion.

An innovation this year is the display of a seri of agricultural films by Mr. More and Dr. Gordon the Department of Agriculture of the University Edinburgh. These will be shown on the Monda afternoon.

THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, ADELAIDE

Opening of New Laboratories

By Sir Charles Martin, C.M.G., F.R.S.

The new Institute of Medical and Veterinary Science was officially opened on May 24 by Sir George Murray, Lieutenant-Governor of South Australia and Chancellor of the University of Adelaide. It represents in part an extension and modification of the pre-existing facilities for the study of pathology, bacteriology and biochemistry at the Adelaide Hospital, which is the School of Medicine of the University; in part, it is a new development:

(1) To carry out, with more adequate accommodation, equipment and staff than heretofore, the routine investigations in the subjects mentioned above for the Adelaide Hospital, Stock and Brands Department, country hospitals and private practitioners.

(2) To engage in research into the causation, diagnosis and cure of disease in man and animals.

(3) By bringing into a building devoted to these purposes the University teaching departments of pathology, bacteriology and applied physiology, as well as a properly equipped clinical lecture theatre previously wanting in Adelaide, to attempt to inculcate in the medical students that appreciation of the significance of laboratory medicine to which at present comparatively little attention is paid, and thus to render their later outlook more truly scientific.

The Institute will work in the closest collaboration with the Adelaide Hospital on one hand and with the University on the other, and adds greatly to the amenities of the Adelaide Medical School.

The Institute is the result of a joint effort on the part of the University and members of the staff of the Hospital to bring together in closer association the Department of Pathology of the University and the pathological services of the Hospital. As the two institutions adjoin there were no topographical reasons why this should not be brought about. The Institute is located in the grounds of the Hospital. It faces Frome Avenue, on the opposite side of which is the University campus. It extends backwards amidst the hospital buildings, which are arranged on the pavilion system. It is, therefore, suitably placed for service to the Hospital and readily accessible to patients. It is also close to the other scientific institutes of the University and to the University library. The style is Georgian, with a pleasing simple frontage, and it has been judiciously planned so as to permit of future extension.

In 1936 the authorities were fortunate in securin Dr. E. Weston Hurst for its first director. Shortl afterwards, the University appointed Dr. Hurst t a research professorship which whilst it gives hi the status of a senior officer in the Universit makes no demands upon the director for teachi duties.

Building was not commenced until 1937, so th the details of planning and equipment were able t be made under his supervision, and it is clear fro the description of the arrangement of the Institut that they have been admirably conceived an carried out. Facilities for research have had du consideration.

The Institute has two stories with a half-basemen It contains some twenty laboratories, a library, tw classrooms, a lecture theatre, a complete operatin suite for animals, common rooms for staff an students, offices for the director, and an abunda supply of general service rooms (hot room, cold roo photographic suite, etc.), plenty of store rooms an a workshop.

On the first floor is a museum, 80 ft. × 40 ft., house the collection of specimens of morbid anatom hitherto inadequately accommodated at the Un versity. Perhaps the most notable feature of th Institute is its fine animal house. This is situate 100 yards from the main building. Especial care h evidently been devoted to its construction and equi ment for the breeding of experimental animals an the convenience and accuracy of experimental wor Expense has not been spared for this essential pa of an institute for research in pathology, and it co one tenth as much as the main building.

The total cost has been £53,000. £15,000 w contributed by three notable benefactions, £10,0 by the commissioners of charitable funds and th rest by the Government of South Australia.

The Institute is governed by a council of s representing the Adelaide Hospital, the Universi and the veterinary interests of the State.

The Adelaide Hospital being a Government instit tion, the surrender of a measure of its sovereign and some of its territory required a special Act Parliament. By this Act, the Government undertak to contribute £10,000 a year towards the maintenan of the Institute, the remainder being derived fro the University Chest and by the allocation of certa ust funds at the disposal of the University. As is sual, the provision of a sufficient revenue is left to ick. If the amount of research is to be enough to istify the accommodation, much more than is at resent forthcoming will be required to provide modest alaries for the upkeep of research workers. There is o lack of suitable graduates in Australia who are nxious to devote themselves to investigation if they an see a reasonable prospect of a living wage. At resent they come to Great Britain with Rhodes and eit and other research studentships and when rained remain, as there are not openings for them in heir mother country. This drainage is not too good or Australia.

Both University and Hospital are to be congratulated on having secured convenient modern ccommodation and equipment for teaching and esearch in pathology and for the better treatment f patients and investigation of their diseases. They re still more to be congratulated on having surmounted the difficulties always attending combined action by the two corporate bodies under separate governance.

Close association of pathology with clinical medicine is desirable. A pathological institute can function apart from a hospital, but its scope is restricted, and researches tend to become remote from the immediate problems of human medicine and the workers lack the stimulus to effort which is afforded by contact with the sick.

An unusual feature in the new Institute at Adelaide is the inclusion of the study of animal pathology as one of its main objects. For some years investigations of diseases of farm animals have been carried on at the pathological laboratory at the Adelaide Hospital, the Government providing a veterinary officer and technical staff for the purpose. The continuation of this association of the study of human and animal diseases will be both convenient and advantageous, for pathology has no specific boundaries, and have not most of the recent discoveries in human pathology been, perforce, achieved by experimenting with animals ?

SYNTHETIC SOUND

N *Philips Technical Review* of June, which is edited by the Research Laboratory of Philips Glow Lamp Factory, Eindhoven, Holland, there is an interesting paper on "Synthetic Sound" by J. F. Schouten. A sound of prescribed character of periodic vibrations, in other words, a sound consisting of harmonic omponents of prescribed amplitude and phase, is btained synthetically. This method permits a closer study of a number of problems which are onnected with the nature of the perception of sound. The principle used is to make a beam of light vary as a function of the time in the desired wave form. The beam is incident on a photo-electric cell and ctuates a loud-speaker. A paper stencil is made nd is uniformly illuminated by a point source of ght from a tungsten arc lamp placed at a considerable distance away. Behind the stencil there is a rotating aluminium disk in which nine slits have been made, each with a width of 1 mm. and at istances of 40° from each other. Behind the disk, which is driven by a motor, is a lens which focuses the light source upon the photo-electric cell. The only light which can fall upon the photo-electric cell is that which has passed through the part of the stencil cut away and one of the slits. When the disk is turning, the amount of light transmitted at each moment is proportional to the height of the part cut away at the point behind which there is a slit at that moment.

The centre of the wave form is situated on the extension of the axle of the motor. With the arrangement used negative values of the light transmissibility annot be produced, and so a constant quantity equal to the largest negative value occurring is added to all the ordinates of the wave form to be reproduced. The frequency was determined by regulating the number of revolutions per minute of the motor. If the desired form is given as the sum of a number of sine-shaped components, the components can be added and the resultant wave form cut out. It is easy to cut out the forms separately one above the other.

An attractive property of this apparatus is that it makes it possible to study directly the influence exerted on sound perception by changes in the wave form. For example, when several components have been cut out one above the other, any one of these components can be made to disappear, simply by screening this part of the stencil from the light.

According to a law of acoustics which was formulated by Ohm, a definite pure tone will be observed in a synthetic sound, when a component of the frequency in question occurs in the Fourier analysis of the wave form. According to a rule enunciated by Helmholtz, the sound perception will further depend entirely on the relative intensity with which the different components occur and will be independent of the relative phase of these components.

The author accounts for these facts in a simple way, which seems to be permissible anatomically, that there are in the ear a large number of resonators tuned for different frequencies. This mechanism explains in the first place the fact that the ear carries out, as it were, a Fourier analysis of the sound while it furthermore makes it possible to suppose that the stimuli which are sent from each resonator to the brain depend exclusively upon the intensity, and not upon the phase of the component in question. The author shows how to test this rule by his apparatus.

Four wave forms were built up of very different shape but all having the same harmonics from 1 to 20. It was found that these four totally different wave forms were quite indistinguishable as to their sound impression. It is also stated that non-linear distortion occurs in the ear. This is manifested by the fact that when a pure tone of sufficient intensity is heard, higher harmonics are formed in the ear; when two tones of different frequency are heard at the same time, new tones are formed with frequencies which are linear combinations of the two tones heard (combination tones). The most obvious combination tone is the difference tone and this is the one that was first discovered.

FORTHCOMING EVENTS

British Association for the Advancement of Science (Dundee Meeting).

Wednesday, August 30

At 8.30 p.m.—Sir Albert Seward, F.R.S.: "The Western Isles through the Mists of Ages" (Presidential Address).

Thursday, August 31

At 10 a.m.—Prof. E. K. Rideal, F.R.S.: "Film Reactions as a New Approach to Biology" (Presidential Address: Section B).

Prof. J. Ritchie: "Perspectives in Evolution" (Presidential Address: Section D).

H. E. Wimperis: "The Future of Flying" (Presidential Address: Section G).

A. Mackay, Dr. W. B. Inglis, A. Cavalcanti, Oliver Bell, R. Ford, W. Farr: Session on Films (Section J).

Dr. A. P. M. Fleming: "Education for Industry" (Presidential Address: Section L).

Sir Thomas Middleton: "Practice with Science: the Farmer's Position and the Scientific Worker's Programme" (Presidential Address: Section M).

At 10.30 a.m.—Dr. S. E. Wilson, Dr. M. L. Anderson, J. A. B. Macdonald, J. M. Murray, F. Story: "Larches" (Discussion: Section K*).

At 11 a.m.—W. O. Lester Smith, Dr. K. Fisher, B. Mouat Jones, Dr. J. A. Bowie: "Education as a Preparation for Industry" (Discussion: Section L).

At 11.30 a.m.—R. S. Whipple: "Instruments in Science and Industry" (Presidential Address: Section A).

Prof. R. A. Peters, F.R.S., Dr. M. Dixon, Dr. H. Theorell, Dr. D. E. Green, Sir F. Gowland Hopkins: "Tissue Respiration" (Discussion: Sections B and I).

Prof. E. G. R. Taylor: "The Proposed National Atlas" (Joint Discussion: Sections C, D, E, F, H, K, M).

At 2 p.m.—W. R. Day: "Larches" (Discussion continued: Section K*).

At 2.15 p.m.—Prof. D. Keilin, F.R.S., Dr. F. Dickens, Dr. H. A. Krebs, Dr. T. Mann, Dr. J. H. Quastel, Dr. S. Ochoa, Prof. H. S. Raper, F.R.S., Dr. E. P. Poulton: "Tissue Respiration" (Joint Discussion, continued: Sections B and I).

Prof. A. Vandel, Dr. A. P. Sanderson, Miss M. C. Malcolm, Prof. A. D. Peacock: "Aspects of Parthenogenesis" (Discussion: Section D).

At 2.30 p.m.—(*a*) Dr. J. S. Huxley: Interim report on inquiry into organisation of research in Britain; (*b*) A. M. Carr-Saunders: "Population Problems" (Division for Social and International Relations of Science).

Friday, September 1

At 10 a.m.—Dr. J. Lawrence, Dr. W. B. Lewis, Dr. L. H. Gray and Dr. J. Read: "Artificial Radioactivity and its Applications" (Discussion: Section A).

Dr. H. W. Melville, Prof. S. Sugden, F.R.S., Prof. W. F. K. Wynne-Jones, Dr. M. Ritchie, Prof. T. Alty: "New Technique in Physical Chemistry" (Discussion: Section B).

W. J. M. Menzies, P. R. C. Macfarlane, Dr. K. Carpenter, R. M. Neill, Prof. J. H. Orton and J. W. Jones, D. F. Leney: "The Habits of Salmon and Trout" (Discussion: Section D).

Prof. W. E. Le Gros Clark, F.R.S.: "The Scope and Limitations of Physical Anthropology" (Presidential Address: Section H).

R. J. Bartlett: "Measurement in Psychology" (Presidential Address: Section J).

Prof. D. Thoday: "Interpretation of Plant Structure" (Presidential Address: Section K).

J. B. Longmuir, G. L. Darbyshire, F. T. Chapma Principal J. Cameron Smail, Prof. W. Jackson, C. Oakley: "Education in Industry" (Discussion: Section L).

G. MacGregor, A. R. Wannop and Prof. N. M. Comber "Agricultural Education" (Section M).

S. G. Barker, W. G. Macmillan, H. L. Parsons, D. Carte H. A. Elkin, Col. J. C. Brockbank, H. C. Bryson, D. Oury: Special Session on Jute.

At 10.40 a.m.—Prof. D. Waterston, Prof. J. Morley, Pro B. A. McSwiney and Dr. B. M. Unkauf, Prof. J. Moir, Prof. E. D. Adrian, F.R.S., T. F. Todd: "Th Problem of Pain" (Discussion: Section I).

At 11 a.m.—A. Stevens: Presidential Address (Sectio E).

At 11.15 a.m.—Dr. J. B. Simpson, Dr. E. M. Anderso Dr. M. Macgregor, Dr. R. Campbell, C. F. Davidso F. W. Anderson: "The Raised Beaches of the Fort and Tay" (Discussion: Section C).

At 2.15 p.m.—Exhibition of Biological Films in th 'Cinerama' Picture House (Section D).

Conference of Delegates of Corresponding Societie Prof. H. L. Hawkins, F.R.S.: President.

At 5 p.m.—Sir Frank Stockdale: "The Application Economic Botany in the Tropics".

Saturday, September 2

At 10 a.m.—Prof. E. A. Milne, F.R.S., Dr. G. P. Tarran K. Snell, Prof. R. Peierls: "The Teaching of Mec anics" (Discussion: Section A*).

APPOINTMENTS VACANT

Applications are invited for the following appointments on before the dates mentioned:

Inspector for Livestock Duties (unestablished)—The Secretar Establishment Branch, Department of Agriculture for Scotland, St. Andrew Square, Edinburgh 2 (September 2).

Instructor in Electrical Engineering and an Instructor Mechanical Engineering at the Constantine Technical Colleg Middlesbrough—The Director of Education, Education Offic Woodlands Road, Middlesbrough (September 4).

A Scientific Officer (Engineer) at the Road Research Laborator Harmondsworth—The Establishment Officer, Department of Scie tific and Industrial Research, 16 Old Queen Street, S.W.1 (quoti J.39/10) (September 5).

Assistant Drainage Engineers (temporary) in connexion wi Land Drainage schemes—The Secretary, Ministry of Agriculture a Fisheries, 10 Whitehall Place, S.W.1 (September 8).

Scientific Officers (Ref. No. B.3430) in the Air Ministry Scie tific Research Pool, and Assistants Grade II (Ref. No. B.3440)—T Chief Superintendent, Royal Aircraft Establishment, South Far borough, Hants (September 8).

A Research Physicist for the Department of Glass Technology The Registrar, University, Sheffield (September 9).

A Statistical Officer at the General Register Office—The Regi trar-General, Somerset House, W.C.2 (September 25).

Meteorological Officer Cadets in the Department of Indust and Commerce—The Secretary, Civil Service Commission, 45 Upp O'Connell Street, Dublin (September 28).

Professional Officer (Field Husbandry) in the Department Agriculture and Forestry of the Union of South Africa—The Secreta Office of the High Commissioner for the Union of South Africa, Sou Africa House, Trafalgar Square, W.C.2 (September 30).

Lecturer in Agricultural Chemistry in the University Sydney—The Secretary, Universities Bureau of the British Emp 88a Gower Street, W.C.1 (October 15).

A Cotton Botanist—The Secretary, Indian Central Cotton Co mittee, Vulcan House, Nicol Road, Fort, Bombay (October 20).

Civilian Education Officers, Grade III, in the R.A.F. Education Service—The Under-Secretary of State, Air Ministry (S.2.I.) (R.M.P. Adastral House, Kingsway, W.C.2.

Assistants (Grade III) in Research Departments—The Establis ment Officer, Department of Scientific and Industrial Research, Old Queen Street, S.W.1 (quoting A/139).

Assistant Advisory Officer to the Board of Greenkeep Research—The Director, St. Ives Research Station, Bingley, Yorks.

A PALÆOBOTANICAL RETROSPECT

IT is one of the privileges of the study of science to-day that it gives to the student a perspective and a sense of proportion that has a wonderfully steadying effect in these anxious days, and thanks to the happy decision of Sir Albert Seward to leave technicalities aside in his presidential address to the British Association, which is printed in the Supplement to this issue of NATURE, his listeners and his readers have had their thoughts tuned to a sense of distance and of time which permits a saner contemplation of the present temporary European turmoil.

No subject could be more appropriate for contemplation by a Scottish audience, or indeed by any British audience, at this holiday season, than a retrospective survey of one of the most popular holiday retreats, the Western Isles of Scotland; but the simple language in which problems of the widest import and of the most intriguing nature are expounded, makes the address at the same time a fascinating example of the scientific method in operation—as Sir Albert expresses it "of how a student asks questions of Nature and does his best to interpret the answers". For a few magic minutes it must have been a great joy to his listeners to yield themselves completely to the direction of so competent and persuasive a guide, and with him to take an excursion "into a world that knew not man", for the Western Isles are contemplated when they were part of a great continent, the Thulean continent or province, at a time some sixty million years ago, and human beings have not appeared upon the scene until all but one fiftieth of this period has transpired.

If thus vast tracts of time are passed in review and at the same time problems raised which demand a mental grasp of distances that cover a large part of the northern hemisphere, the picture is built up by a creative imagination working with the most scrupulous regard for detail, and probably no feature of the address would more impress the newcomer to such problems than the suggestive use that is made of careful, detailed observations upon fossil plant material, the debris perhaps of a forest floor, preserved through the ages by the processes of sedimentation or the fortuitous action of volcanic agencies. The detailed sculpturing of a pollen grain needs microscopic examination with careful optical control, but through it may be built up a 'spectrum' of pollen dispersion in peat or coal which is as revealing to the botanist as is the spectrum of a star to the astronomer. Careful methods of clearing may render details visible in a fossil cuticle which permit the recognition of a microscopic leaf parasite and thus some suggestion as to the moisture of the climate in which this leaf-born cuticle had flourished. The student of the living plant must admit that if he had studied details of form and venation of leaves with the thoroughness of his palæobotanical colleague, very often his claims as to the affinities of living plants would be more securely founded.

Sir Albert's reconstruction of the Thulean forest is based in part upon the earlier collections from the plant-containing beds of the islands of the Inner Hebrides, and particularly the layers near the base of the basaltic lavas on Ardtum Head, near the south-western corner of Mull, but it is based mainly upon recent and as yet unpublished data obtained by Sir Albert himself, in association with Mr. W. N. Edwards, keeper of geology in the British Museum, and Dr. J. B. Simpson of the

Geological Survey; they are, then, the result of a felicitous partnership of botanists and geologists and illumine the field of study of both sciences.

The conifers of this corner of the globe in these far-off days were certainly more varied and diverse than the Forestry Commission would venture to utilize in trying once more to reclothe their rocky flanks and mist-swept valleys with forest. *Sequoia sempervirens* they might plant, and also Abies, but Cryptomeria and Cephalotaxus are surprising genera to find in a Hebridean flora; they are confined to-day to the Far East, as is also that other remarkable gymnosperm, *Ginkgo biloba*, the maidenhair tree, a doubtful native now of any country but still much valued in cultivation in China and Japan.

Indeed one striking result of this survey is the remarkable preponderance in the probable generic sources of fossil pollen, and in the debris of woody gymnosperms and angiosperms, of generic names which now are associated with the flora of the Far East. Many a keen gardener in Sir Albert's audience—and in a Scottish audience there would be many—must have been intrigued to realize that, in introducing to the garden such plants as Cercidiphyllum for its beautiful autumnal foliage, or such a flowering shrub as an Abelia, he was re-introducing to a Hebridean environment a genus which flourished in the Thulean forest sixty million years ago; the wheel has come full circle.

It is evident that the former existence of this vast continent, reaching into the Arctic Circle and linking North America through Greenland with Europe and even the Far East, has considerable significance in relation to problems of plant distribution of the present day—a point that is made clear by Sir Albert's suggestive discussion of selected genera of flowering plants. This naturally leads to a reference to hypotheses of drifting continents, discussed by Prof. W. W. Watts at the Norwich meeting of the Association. Sir Albert recognizes that geophysical methods of precision have as yet failed to furnish evidence of any sliding of the earth's crust, but he points out that "geologists and palæontologists contribute facts that are incontrovertible however much they seem to be in opposition to the views of students whose primary interest is in geophysical problems".

On such vexed questions of evolution as the origin of the flower and the angiosperm carpel, this Hebridean flora of sixty million years ago is silent. So comparatively recent a time is this in terms of evolutionary processes, that the forest has already taken on the general aspects of a modern sub-tropical forest with seed plants dominant.

Sir Albert discussed in this connexion the fascinating problems raised by Prof. T. M. Harris's observations upon forest beds at Scoresby Sound in Eastern Greenland, which suggest that a luxuriant and uniform vegetation once occupied an area stretching from central Germany to southern Sweden and a thousand miles farther north, beyond latitude 70° N. In those days arctic voyagers, had there been any, might have felled tall trees for their masts within the Arctic Circle, and the fossil records from both arctic and antarctic regions are a constant reminder that the problems of climate of past time raise questions of far-reaching implication.

In fact the address showed how the palæobotanical approach stimulates interest, gives significance to the minutest detail and adds depth and width to our contemplation of everyday phenomena. Inevitably, therefore, the thought arises, as it emerged at the end of the address, why is this enrichment of everyday experience usually denied to us during school years. But a plea for the introduction of geology to a curriculum which is already so overloaded that even biology still often demands a place in vain is scarcely likely to receive more than a sympathetic hearing.

Perhaps the solution is along the lines followed now in an increasing number of schools, where up to the School Certificate stage the formal divisions of science are no longer recognized and general science is studied; when the material for exercises in scientific method can thus be selected in accordance with their claim upon experience, the soil will certainly win its way into the class-room and thus, for certain schools, where perhaps some member of the staff has made contact with geology in his years at the university, the rocks and their story and that of the agencies at work moulding the earth on which we live will be permitted to weave their own spells upon the unspoilt imaginations of the coming generation, which may thus become alive to the possibilities of interest which the subject holds. It will then perhaps add still more, for a coming generation, to the foundation of a serenity of outlook and saneness of poise, conspicuous in this year's president, which if more widely spread among us, would to-day have its definite value in preserving the community from the onslaught of the 'war of nerves' now so loudly proclaimed as in full spate.

THE FUTURE OF MANKIND

The Fate of Homo Sapiens
An Unemotional Statement of the Things that are Happening to him Now, and of the Immediate Possibilities Confronting Him. By H. G. Wells. Pp. vi+330. (London: Martin Secker and Warburg, Ltd., 1939.) 7*s*. 6*d*. net.

NO one having reached maturity in the reign of Queen Victoria and having survived into our present epoch can be expected to feel altogether at home. In those days, distant not so much in time as in atmosphere, although everyone believed in inevitable progress, "there was a widespread feeling that nothing more of primary importance was ever likely to happen". It was precisely because of this static condition of things that the public so eagerly took to Mr. Wells's futuristic romances.

But all that has changed; the dominant question is: What is likely to happen? And the answers given to it are disturbing. Mr. Wells's answer is no exception:

> "There is no reason whatever to believe that the order of nature has any greater bias in favour of man than it had in favour of the ichthyosaur. . . . I perceive that now the universe is bored with him, is turning a hard face to him, and I see him being carried less and less intelligently and more and more rapidly . . . along the stream of fate to degradation, suffering and death."

Mr. Wells does not consider that this fate is as yet absolutely inevitable, though to escape it there will have to be something in the nature of a wholesale conversion of the species to more rational habits of thinking and behaving; and he does not appear to believe that this is very likely to happen.

The gravest menace to humanity at present springs, as everyone recognizes, from war. The Marxists regard war as a natural symptom of an economic system in decay; but Mr. Wells repudiates Marxism. For him, war has been from primitive times a natural form of social blood-letting, caused by a surplus of young men. In the pre-scientific epoch only relatively puny means of destruction were available. But the inventive urge of the species has altered the situation for the worse. Instead of being "part of the accepted human rhythm", war has become "a galloping consumption of the human species".

Thus a situation has developed which threatens the human race with decline and ultimate extinction. The question is: Are human powers of self-adaptation sufficient to enable the species to adjust itself to this new situation? The trouble is that speed seems to be called for; there is no time for the older and slower methods of adaptation. Of course, man's possession of a unique brain gives him an advantage; and the readjustment will have to be a *mental* one. This mental readjustment, says Mr. Wells, must involve three main essentials: (1) the idea and tradition of war must be eliminated; (2) "The vast and violent wastage of natural resources in the hunt for private profit, that went on in the nineteenth century, must be arrested and reversed by the establishment of a collective economy for the whole world"; (3) the resultant world organization must be "of an active, progressive, imaginatively exciting nature", so that the surplus energy of youth may be absorbed by it and not allowed to run to destructive waste in war.

These three principles, peace, collectivism, and incessant new enterprise, are interdependent and inseparable. In Mr. Wells's view, the League Covenant failed because it completely disregarded these principles. It overlooked the problem of the restless young men; and it gave no attention to "the absolute necessity of reconstructing economic life upon a collectivist basis throughout the world".

In order to bring about the mental adjustment involving acceptance of his three principles, Mr. Wells calls for "such a *kultur-kampf* as the world has never seen before". Nothing less than the entire reconditioning of our mental life is required. What our generation needs is the kind of enlightenment that the French encyclopædists provided in the eighteenth century. It was the ideas of Diderot and his associates that "materialised in the American and French revolutions and in a great heartening of the creative spirit of man". Is it possible for this achievement to repeat itself on a larger scale to-day?

Mr. Wells does not believe that our present educational institutions are likely to effect the change. The common schools "are essentially conservative institutions, adapting the common man to the social order in which he finds himself", and they fail to provide "the scientific vision of life in the universe". Thus the existing educational organization "needs to be recast quite as much and even more than the political framework".

It will be plain that what is here advocated is nothing less than a complete change of mentality, a redirection of public interest. The question is whether a new programme of intellectual education, even of the most enlightened kind, would suffice to achieve the change. The real trouble is that the educated, even those with an education in natural science, can be enlightened intellectually, without being in the least enlightened emotionally. What is needed is a transvaluation of values, and this is not to be achieved easily. Mr. Herbert Read has suggested that we should "try the experiment of educating the instincts instead of suppressing them". Many educationists (who as a class are very much more progressive and alive to realities than Mr. Wells would seem to be aware) are trying to work along these lines, but it is work that will not be done in a day. Meanwhile, as Mr. Wells says, the need is urgent.

This is a timely and sincere book and written without fear of giving offence. J. C. H.

TRADITIONS AND FUTURE OF BRITISH DEMOCRACY

The Anglo-Saxon Tradition
By George Catlin. Pp. xii+286. (London: Kegan Paul and Co., Ltd., 1939.) 10*s*. 6*d*. net.

THE Anglo-Saxon tradition has "impregnated the political institutions of the Anglo-Saxon world on both sides of the Atlantic and has provided patterns to all Europe and to the lands that look to Europe". Prof. Catlin seeks, in this book, to re-clarify the political and moral content of that tradition and to derive from it guidance as to the course which should now be taken by the Anglo-Saxon peoples. This tradition is contrasted with the conception of man's purpose in the world that arises from Fascist and Communist ideology.

Whatever may be the truth for German and Russian minds in these concepts, they are not for British. The fulfilment of life in the Anglo-Saxon meaning is in the preservation of our own cultural traditions, while we carry out the changes in economic and social organization that are necessary so that this tradition may flower and bear fruit for all the citizens instead of, as now, mainly for a favoured few. Prof. Catlin urges upon us that if we are to serve our mission in the world we must develop a new vigour of thought and action inspired by humanist philosophy. Only by moving forward with courage and wisdom in the light of our own cultural history will we be saved from drifting unwittingly into errors which will make us appendages to one or other of the totalitarian camps.

The Anglo-Saxon populations of the British Empire should be bound closer together in economic and political co-operation. They have an immense opportunity and responsibility to develop the vast area of the Colonial Empire "until the time comes to transfer it, as a substantial basis of wealth and power and a *peculium* to the direct rule of Geneva or a World State which requires such sovereign possession to give it dignity". They should take the first step towards a new federalism in the world by establishing now a community of interest in all fields with the United States of America.

Perhaps the most striking thing about the book is that, while it is written by a member of the Labour Party, it expresses a view with regard to the mode of economic, social and political evolution which will be acceptable to all Conservatives of progressive mind. The pressure of crises, economic and political, in the modern world, is producing such new formulations of policy as to make the party alignments preposterous There are many things which Prof. Catlin says that I do not agree with. Curiously enough, the main theme of my criticism would be that he is too hard upon the Soviet Union. I should have interpreted its experiment as having a far greater content of social value and of progress than this book gives it credit for. On the other hand, I should have been less tolerant of the German Nazis than, in some passages, he appears to be. There are differences of emphasis but they are of a kind which show how completely obsolete is the old party conflict.

The main contentions of the book are stimulating; they form a valuable contribution to a current of opinion which has been growing in strength in recent times. The issues dealt with are of vital importance to ourselves and to the world. Those who appreciate that we are not going to find our way out of the present impasse without some hard thinking would do well to read this book with care.

H. MACMILLAN.

MAGNETISM: OLD PROBLEMS AND NEW METHODS

(1) Ferromagnetism
The Development of a General Equation to Magnetism. By Dr. J. R. Ashworth. Pp. xiii+97. (London: Taylor and Francis, Ltd., 1938.) 7*s*. 6*d*. net.

(2) Modern Magnetism
By Prof. L. F. Bates. Pp. ix+340. (Cambridge: At the University Press, 1939.) 16*s*. net.

ALTHOUGH the books of Dr. Ashworth and Prof. Bates both deal with aspects of magnetism, their difference in character and purpose is such as to illustrate very forcibly the limitations of any formal system of book classification by title or subject.

(1) Dr. Ashworth has performed a useful service in collecting together, in abbreviated form, his own contributions to magnetism It is more than forty years since he published his first paper on the subject; but most of the twenty-two papers listed have appeared since 1912. The experimental work described includes extensive investigations on the temperature and field dependence of the magnetization of iron, nickel and cobalt, with particular reference to anhysteretic properties, studies of the temperature coefficient of magnets, and measurements of specific heat. In the attempt to develop a general equation covering ferromagnetic behaviour, to which much attention is devoted, use is made of an equation having formal analogies with the van der Waals equation of state for fluids. In this ferromagnetic equation of state, field and intensity of magnetization correspond to pressure and density, and the reciprocal of the paramagnetic Curie constant to the gas constant in the fluid equation. Critical constants are evaluated for the different ferromagnetic materials, and empirical relations between these constants are obtained.

In seeking to correlate a wide range of facts in this particular way, Dr. Ashworth has pursued a very independent course. Many of the relations are striking, but as the task of tracing their significance in the light of the interpretation of ferromagnetism which is now generally adopted is not undertaken, most readers will be left in a state of doubt as to what has, in fact, been achieved. The answer would appear to be that there is a considerable amount of purely empirical correlation covering a limited range of ferromagnetic phenomena, which may be useful for empirical purposes, but that, without much further consideration and development, the fundamental significance of the relations obtained remains obscure. In spite of this drawback in the treatment of one of the main themes, the book is well worth examination by those concerned with magnetism, just because of its almost complete independence of approach to the problem of ferromagnetism. Moreover, some of the experimental investigations are along lines which for some time have been rather neglected, but are now again becoming of central interest.

(2) Prof. Bates, who collaborated in some of the earliest successful investigations on the gyromagnetic effect, and whose subsequent researches have been mainly concerned with magnetism, has written a general survey of recent work. He has been impressed by the difficulty found by students in acquiring a satisfactory knowledge of magnetism, and he believes this to be largely due to the subject having been treated far too much from a strict theoretical point of view. He has, accordingly, given prominence to the description of fundamental experiments. The theoretical side is not excluded—indeed, the first chapter gives a very comprehensive account of the classical and quantum theoretical background—but usually questions of theoretical interpretation are considered only briefly in connexion with experimental work to which they are relevant.

There are good accounts of methods for the production and measurement of fields, and for examining the magnetic properties of isotropic substances and crystals. The details given of the more widely applicable methods, and the practical comments, will provide a most useful guide to those embarking on similar work. Adequate footnote references will facilitate the task of finding fuller information. There are shorter descriptions of more specialized apparatus.

Some of the most outstanding examples of recent experimental technique are admirably presented in chapters on atomic and nuclear moments, and on the gyromagnetic effect. The last part of the book deals mainly with ferromagnetism. Methods for the measurement of saturation magnetization and the determination of the Curie point are described, the general theory is outlined, and there are accounts of the magnetic properties of metals and alloys. The various magneto-thermal effects are fully considered. Finally, a résumé is given of work on magnetostriction and the Barkhausen effect.

Inevitably, in a book of this kind, there is some overlapping with other books dealing generally with magnetism, but the author has chosen his main topics so as to include a considerable amount of material "which a student cannot readily find elsewhere". Though the book, if considered alone, might seem to give a rather ill-balanced survey of the field of magnetism, when considered in relation to other books, it is just this lack of balance which makes it a most useful addition to the literature of the subject. The author's own work has been very varied, and in writing of experimental technique, he includes information of a kind which could only have been gained from practical experience. The book will be particularly valuable to those carrying out experimental work on magnetism. The clear presentation will appeal to the student, and the account of much recent work will be appreciated by physicists and others who wish to keep up to date with the subject.

In one of these two books the author, who has zealously followed up an individual line of inquiry, presents his findings almost unconcerned with their relations to the wider scheme. In the other, the author surveys a wide range of work with a keen appreciation, and with a sense of the interlocking character of scientific investigations. The books present, on one hand, a particular approach to an old problem, and on the other, a broad survey of the new methods for attacking this problem and others related to it. E. C. S.

THE LIVING PLANT

Botany of the Living Plant
By Prof. F. O. Bower. Third edition. With the Assistance of Prof. J. M. F. Drummond and Dr. George Bond. Pp. xii + 700. (London: Macmillan and Co., Ltd., 1939.) 25s. net.

PROF. BOWER'S text-book is so well known for its many excellent qualities that it needs no introduction to British students and teachers. It is evident, however, that during the sixteen years which have elapsed since the second edition was published, many fresh discoveries have been made which it is desirable to include in an up-to-date text-book. In preparing this new edition Prof. Bower has been assisted by Prof. J. M. F. Drummond and Dr. G. Bond.

No change has been made in the general arrangement of the book, which was fully described in NATURE at the time when the first and second editions appeared (NATURE, 104, 274; 1919: 112, 51; 1923); but the sections dealing with certain aspects of plant physiology, cytology and genetics have been largely rewritten or amplified. In particular the chapter on the living cell has been considerably modified, and there is new information on the internal regulation of growth by plant hormones, and also on the influence of the length of day on the flowering of plants.

The sections dealing with mycorrhiza and the fixation of nitrogen by the bacteria present in the root nodules of leguminous plants have also been considerably modified. Recent advances in cytology are well summarized, although necessarily in a somewhat condensed form, and the relationships of cytology to genetics and between genetics and evolution are discussed. There is also a short article on vitamins. On the morphological side the most interesting innovations include a section dealing with the Psilophytales, a more complete treatment of the Equisetales, and a new discussion of the origin and significance of alternation of generations.

The author has also included a chapter on the relation of size and form in plants. In this he cites and discusses examples which support his working hypothesis that "Elaboration of form as the size of the individual increases is a means of maintaining the surface-volume ratio, which would otherwise tend to fall to a point of physiological inefficiency". Prof. Bower admits quite candidly that his views on this subject are not yet fully proved, but he asks meanwhile that his readers shall maintain that "wholesome frame of mind styled by Huxley as 'suspended judgment' until by extended observation this theory of Size and Form shall have been either disproved, or raised to a level of reasonable probability, with Galileo's Principle of Similarity as its foundation". He makes the interesting speculation that the primary form of a plant may be initiated by a hormone "under control of the apical cone".

As one would expect, the book is characterized by a welcome simplicity of expression throughout, and no intelligent student can complain of inability to understand its contents. Opinions differ from time to time concerning what should or should not be included in a text-book of botany, and in these days of specialization it may be felt by some whose botanical interests are somewhat circumscribed, that their own particular subjects have not received adequate attention. But it is difficult to see how a more balanced and broad-minded introduction to general botany could have been written. It is much to be hoped that it will be even more generally used than the two earlier editions.

C. R. METCALFE.

ELECTRON OPTICS

(1) Electron Optics

Theoretical and Practical. By L. M. Myers. Pp. xviii+618+68 plates. (London: Chapman and Hall, Ltd., 1939.) 42*s*. net.

(2) Theory and Applications of Electron Tubes

By Prof. H. J. Reich. Pp. xviii+670. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 30*s*.

(3) Fundamental Electronics and Vacuum Tubes

By Prof. A. L. Albert. (Engineering Science Series.) Pp. ix+422. (New York: The Macmillan Company, 1938.) 20*s*. net.

(4) Electron Optics

By the Research Staff of Electric and Musical Industries, Ltd. Compiled and written by Otto Klemperer. (Cambridge Physical Tracts.) Pp. x+107. (Cambridge: At the University Press, 1939.) 6*s*. net.

(1) MR. MYERS is to be complimented on producing the first book on the subject to be published in Great Britain, and a truly comprehensive and readable book. He has spared no pains in bringing the matter up to date, and his exhaustive survey of the whole field includes some eight hundred references.

Roughly, the first half of the book is mathematical, and gives the fundamental electron-optical laws and a detailed examination of electric fields which brings in the electron trajectory. This eads up logically to the treatment of various types of electron lenses and their aberrations. The mathematical derivations are supplemented by experimental details which bring out the important applications, but more stress could profitably be aid on the physical interpretation of the formulæ deduced.

The second half of the book is mainly descriptive. t deals with the electron multiplier, electron microscope, and some of the latest developments. The immediate application of electron-optical principles in the discussions of these various devices makes stimulating reading, since the uthor has participated in some of the researches which are described.

On the whole, the book is well balanced. Apart from a number of simple misprints, the illustrations are excellent, particularly those showing ravitational models of the electric field. Aspects f the subject which would enhance the value of the book are (1) a discussion of deflection distortion nd design of deflecting systems, and (2) graphical ray tracing involving a discussion of lens design. The section on the space-charge effect is not clear, and needs further amplifying. A most useful addition would have been a discussion of ion focusing and its application to atomic disintegration research.

(2) It will always remain a matter for argument as to what ought to be included in a book of such wide scope as Prof. Reich's, if the subject is to be adequately treated. The author has made a wise choice of subject-matter. He brings to the student of radio-engineering and the future television engineer just those fundamentals necessary for an intelligent appreciation of this wide field. After two preliminary chapters on the physics of their internal action, the behaviour of vacuum tubes and an analysis of circuit conditions are discussed in eleven chapters.

The introduction of the series expansion for the alternating plate current as well as the numerous applications of graphical analysis should prove most helpful to the student. Glow and arc phenomena are discussed at greater length than is usual. This is all to the good, because of their expanding practical applications. The chapters on photo tubes and instruments dependent for their action on the use of vacuum tubes complete an excellent book. The author has brought all his experience as a teacher to bear in his lucid method of presentation. The large collection of references adds greatly to the value of the book for all engaged in research in these fields.

(3) Prof. A. L. Albert's book can worthily take its place among the excellent group of American works on vacuum tubes which have appeared in the last few years. The author has succeeded in his task of introducing to engineers the fundamental principles of electronics.

The first three chapters are devoted to an examination of sources and methods available for production of electron streams. Their utilization in diodes and multi-electrode valves is fully discussed in the next four chapters. After this, vacuum tube amplifiers, oscillators, and modulators are dealt with. Chapters on photo and cathode ray tubes complete the book.

The treatment is non-mathematical throughout, and the illustrations and numerical applications of formulæ aptly bring home the important points that require stressing. A more graphic and detailed account of the electric field as affecting electron motions would have added to the stimulating explanations given.

The book can be recommended to physicists as well as to engineers.

(4) Mr. Klemperer's monograph is an excellent introduction to the study of electron optics. While written mainly for graduate students, the development of the subject almost from first principles extends its usefulness. The cardinal points of electron lenses determine their behaviour and properties. These are deduced on the basis of field plots, and the parallel optical concepts are neatly worked into the scheme. Other important chapters deal with aberrations and magnetic lenses, and a final chapter is devoted to applications. The author has performed a difficult task very well indeed. His choice of subject-matter as well as his method of giving examples of immediate practical applications of theory should prove most stimulating to all his readers. L. JACOB.

PHARMACEUTICAL CHEMISTRY

(1) Bentley and Driver's Text-Book of Pharmaceutical Chemistry

Revised by Dr. John Edmund Driver. Third edition. Pp. ix + 624. (London: Oxford University Press, 1937.) 16*s*. net.

(2) Drugs and Galenicals: their Quantitative Analysis

By Dr. D. C. Garratt. Pp. xiv + 422. (London: Chapman and Hall, Ltd, 1937.) 25*s*. net.

(1) THE pharmaceutical student has, as a rule, only a short period of intensive and continuous study in which to acquire that somewhat heterogeneous collection of knowledge about the inorganic chemicals, synthetic organic substances and components of natural drugs, which constitutes the pharmaceutical chemistry of an examination syllabus. A large part of this knowledge is concerned with the standards of quality specified for the drugs of the British Pharmacopœia, and the methods by which deviations from these standards may be detected. It is reasonable, therefore, that the authors of this text-book should begin with a series of chapters dealing generally with methods for the characterization and analysis of substances used in medicine, and they have spared no pains to secure clarity and simplicity in their statement and explanation of the principles on which these methods are based.

This section is followed by one dealing with inorganic compounds, written so far as possible on the usual lines of a text-book on inorganic chemistry, but distinguished by the addition of that special information required for therapeutic purposes. Thus, the reader is not told how to prepare oxygen—he should already possess that information—but how it is manufactured, what impurities associated with different manufacturing processes may be present, and how he may ascertain whether these impurities are within the limits allowed by the Pharmacopœia.

More than half of the book is devoted to organic chemistry, dealt with on the usual systematic lines, but with each group of substances illustrated by its outstanding pharmaceutical examples.

By this method of treatment the authors have constructed, from what appears at first to be rather difficult material for systematic exposition, a coherent and well-balanced text-book, which contains much interesting information not usually found in books on chemistry written for students That the book is appreciated by its special clientele is clear from the fact that, since the first issue in 1925, it has been reprinted once, and is now in its third edition.

(2) The first reasonably efficient process for the estimation of morphine in opium was published over half a century ago. Since then there has been a steady output of papers on the same subject and recent activity indicates that even now the last word has not been said. Few other drugs have received so much analytical attention as opium but most of them have had a good deal said about them, possibly because the pharmaceutical analyst is an observant and uncompromising individualist who is happiest in using a method in the evolution of which he has himself played some part, or as Dr. Garratt puts it, "individual bias is often responsible for the fact that a method which is found unreliable by some analysts may, in other hands, give good results". Whatever may be the reason, the literature on drug analysis is enormous and Dr. Garratt has earned the thanks of his fellows by putting into this book the results of his critical survey of this mass of material, and giving them the benefit of his seventeen years' experience as drug analyst to the London County Council in trying, comparing and checking selected methods

The book being intended for professiona analysts, explanations of processes are not given and the familiar British Pharmacopœial methods are not quoted, unless comment has to be made or new applications suggested for them. A particularly useful feature of the book is the inclusion of methods for the analysis of mixtures and compounded drugs of various kinds, and the term drug is not interpreted too narrowly, insecticides such as derris and pyrethrum being also dealt with.

Great pains have been taken to secure accuracy and to achieve completely the objective indicated by the title of the book. Here and there small points can be found to cavil at, but there can be no doubt that the book will prove useful to all whose business it is to be engaged regularly, or occasionally, in the examination of drugs, simple or compounded.

T. A. HENRY.

THE EARTH'S CRUST: ITS FABRIC AND FOUNDATIONS

Architecture of the Earth
By Prof. Reginald Aldworth Daly. (Century Earth Science Series.) Pp. xiii+211+47 plates. (New York and London: D. Appleton-Century Co., Inc., 1938.) 12*s*. 6*d*. net.

IT is on record that Prof. Daly's students, in his practising days, used to chant "Every morning in the year, Daly has a new idea". But Prof. Daly's claims to the gratitude of his scientific brethren lie as much in his popularization of the results of geological research as in his many contributions to its progress. In this volume he takes as his text a happy adaptation by the late Prof. P. Termier, director of the Geological Survey of France, "The earth declares the glory of God", and succeeds in justifying it, telling his story in a manner that the intelligent layman can understand. In this matter of popular scientific writing, a trite remark from the author's preface is worth reproduction: such popularization of science requires "effort by the specialist to be an adequate reporter; effort by listener and reader to imagine".

The "Architecture of the Earth" represents the slightly expanded material of lectures on "The Crust of the Earth", given under the auspices of the Norman Wait Harris Foundation of the Northwestern University in May 1937. Special emphasis is placed on the discoveries and classifications made since the opening of the present century; in particular, new light is thrown on old problems as a result of the recent spectacular growth of the young science of geophysics. Four main problems are selected for study: mountain-building, the eruption of lava, the diversification of rocks once molten, and the stability of continents and island masses. Up-to-date results of the analysis of earthquake records and gravity measurements are utilized.

The author expounds in simple language the thesis he recently published in less accessible form —to the effect that the 'third' layer of the earth's crust consists of glassy basalt rather than ultrabasic rocks like dunite and pyroxenite, as the geophysicists are disposed to postulate Thus the earth-shells consist, from the surface downwards, of Sial (the sedimentary and granitic layer of which the continents are composed), with the 'intermediate' layer, the Sima of crystallized basalt underlying the continents and forming the floor of the oceans, otherwise termed the gabbroic layer, and the 'third' shell of vitreous basalt. Concerning the constitution of these layers as deduced from the behaviour of earthquake waves, Prof. Daly expresses himself as not convinced of the force of the argument that, since a fluid cannot transmit shake- (transverse) waves, and such waves are propagated to depths of 60 km. or more, a vitreous shell cannot exist there. He contends that it still remains to be demonstrated that shake-waves cannot be propagated in melted basalt exposed to a minimum pressure of 17,000 atmospheres. Recalling the fact that Gutenberg, from his earthquake studies, deduced the possibility of a vitreous layer at 60–70 km. depth, he refers to Ide's experiments on the passage of sound waves through Pyrex glass and Volarovitch's statement that, up to a temperature of 1100° C., molten basalt at only one atmosphere of pressure has effective rigidity and can transmit shake-waves. From recent laboratory work, the determination of the velocity of shake-waves suggests that the effect of high temperature somewhat offsets that of high pressure.

Prof. Daly further argues that dunite and pyroxenite (supposed to form the 'third' layer, because specimens of these rocks collected from the earth's surface most nearly satisfy the density and velocity requirements) are actually loose-textured and porous rocks which could not exist in that condition in the depths. He suggests interesting experimental work which would throw light on these and other problems, and looks hopefully in one chapter for a Croesus to supply the funds, and in another to a Maecenas to furnish the equipment. Whether his new views are accepted or not, they are characteristically stimulating, and his well-written and richly illustrated volume is worthy of attention from both specialists and laymen.

P. G. H. BOSWELL.

THE COLLAPSE OF CIVILIZATIONS

AT a time when Western civilization seems to be in danger of self-immolation, and in the East the greatest of Empires has yet to show whether it has lost that power of resilience, which has been its most striking characteristic in the history of a civilization extending over a period reckoned not in centuries, but in millennia, some of us may well turn to the past for a sign which will act as a guide to the underlying laws which govern the rise and decadence of peoples. It is this that justifies a reference, belated though it may seem, to a Friday Evening Discourse at the Royal Institution on "The Collapse of Ancient Civilizations", delivered by Mr. Stanley Casson, on February 24.

Mr. Casson, in surveying the rise and fall of peoples and cultures in antiquity, drew the interesting moral—much to the point in the present stress of rearmament—that whereas war-like aggression was a destructive force, hurrying more often than not to its own destruction, militarism, in the sense of preparedness for war, was an essential of survival. In truth, however, his argument developed a broader implication ; and it may not be without present advantage to see how, when observed through the eyes of an archæologist, the main trends of movement revealed by this department of research afford analogies which may aid in the attainment of a judicial and detached view in perspective when estimating present-day tendencies.

Now Mr. Casson points out that so far as our evidence goes, organized warfare begins with the emergence of man from the simple stage of the food gatherer into the neolithic phase of food-production by agriculture—the food gatherer, who lives from hand to mouth, raids the agriculturist in order to seize his surplus supplies of food. The agriculturist—short of becoming a serf, as might have been pointed out—survives only on condition that he organizes a successful system of defence. "So War, the scourge of mankind developed", while militarism, using the term in no derogatory sense, came into being "for the purpose of dealing with War—a part of civilization—its defensive aspect". In other words, "war is the biological process by which a less developed or successful people attempts to get something for nothing, by simple seizure, by violence and by assault", while "the immediate response of the civilized community to imminent warfare is defence, and defence implies what can be called Militarism".

Mr. Casson proceeds to develop his thesis by examining in broad outline the development of ancient civilizations, beginning, naturally, with that of the Sumerians in Mesopotamia. Thus the earliest written records of the Sumerians relate on one hand to the storage of surplus corn, on the other to wars and the treaties which concluded them. There is a further significance in the fact that this surplus of corn had given rise to a leisured class, the priests, who controlled it, and they also controlled education, another consequence of the existence of a surplus. Again, almost as soon as they had perfected the urban mode of life, which is their great cultural legacy to the world, they also perfected a defensive machine with which to protect it. They created an army to defend themselves against the less cultured peoples, possibly still food-gatherers of the mountains to the east, and devoted to it all their intellectual gifts. By the end of the fourth millennium, they possessed armaments which "anticipate by many centuries those of the Homeric and Classical Greeks". Walls and an organized army preserved civilization in its earliest stages ; and, Mr. Casson argues, so firmly did this militaristic defence establish it, that civilization in Mesopotamia survived in fact longer and with more persistence than in any other part of the globe.

This may seem a hard saying, in view of the duration attributed by tradition to the civilization of China, which goes back to a date little, if at all later, than that of Mesopotamia ; but Mr. Casson makes his meaning clear when he goes on to argue and to demonstrate that the civilization founded by the Sumerians not only contributed to the foundation of European civilization—he is evidently a diffusionist—but also endured in an unbroken stream, notwithstanding dynastic and racial changes, though subject to interruption by the Mongols, down to historical, or even, it might be said, to present-day times. In all this period, he points out, there has been no collapse of civilization, no real breakdown.

Turning to Egypt, there is here too an immensely ancient mode of life, largely conditioned by geographical and physical factors, which survived. While its history runs concurrently with Mesopotamian, neither Greece nor Rome were ever more than superficial controls on Egypt. Egyptian culture was too deep-seated, too well-protected to be displaced. Its protection was the desert, which flanked its valley, and the excellent organization of its armies. It survived the attacks of the sea-raiders of the thirteenth century B.C., the Libyans, the Bedouins, and the nomads, who came to raid it and seize its surplus wealth. "Egypt was throughout her history, as well organized against barbarian as was Sumer."

Mr. Casson is fully alive to the importance of the negative instances which lend their support to his theory. These he finds in Crete and the Hittites. Crete, he points out, is "the first complete collapse of a complete civilization". On the basis of a culture derived from the Middle East and to some degree influenced by Egypt, the Cretans forged a peculiar and unique civilization unlike any other before or since. Living on an island surrounded by a sea, difficult even for large ships to-day, they were isolated and free from attack. Therefore, unlike Sumerians and Egyptians, they had no standing army, no militaristic organization, other than for ceremonial, and no navy. Apparently they depended on the fact that the barbarous peoples of the mainlands would be unequipped to cross the dangerous seas to attack them; and so they built no walls. Unwisely, however, they conveyed to those barbarous peoples some knowledge of their wealth and culture; and it is therefore scarcely likely to be accidental that at the very time that Cnossos wanes, Mycenæ waxes. Though it cannot be proved as yet, it is a sufficiently satisfactory working hypothesis that when about 1400 B.C. the whole civilization of Crete crumbles and collapses, it may have been due to the barbarous Greek-speaking peoples of the mainland, the forerunners of the heroic period. It is instructive to note that the Myceneans adopted the externals of Cretan culture, rather than its intimate spirit. Mycenean culture is both cruder and more magnificent than Cretan.

An even more instructive point which Mr. Casson makes is that this great heroic age, of which Homer sang, did not endure. "Examine history," says Mr. Casson, "and you will always find that heroes have little lasting power or survival value. . . . The heroes of an heroic age are busily engaged in squandering the accumulated capital of their predecessors, and living on the carcase of a higher civilization than their own." The Homeric civilization in its brief duration and decadence finds a parallel in the heroic age of England after the departure of the Romans, and in Ireland, as well as in the exploits of the Crusaders in Byzantine history.

Again, of the Hittites, without following the details here, it may be said that the fall of the Hittite Empire—the empire of a people who left us no heritage of culture and had no survival value—is to be attributed to the fact that they allowed a people more barbarous than themselves to encroach on the south and west, and lived with a permanent open door at the back of their fortress. They ignored Europe and Europe destroyed them.

A pregnant contrast is afforded in the respective fates of Greece and Rome. Rome perished and Greece survived. For in the Byzantine Empire—Greek in spirit, in intelligence and in organization, in all three of which it was superior to Rome at any period—Greek culture persisted nearly a thousand years longer than the main structure of Roman culture. Roman culture, even if it left the indelible marks of its great civilization on some of the peoples of Europe, for their eternal advantage, passed away as a complex structure of civilization as certainly as did the Hittite.

The inferences which Mr. Casson draws provisionally at this point may be stated as follows:

(1) A civilization that lives in a world, where there are deeply marked divergences of culture and development, must be fully defended to survive. Its defence must take the form, as did the defence of Byzantium, of attack, if necessary, and of alertness always. As Mr. H. G. Wells has said, "An empire that awaits attack is doomed".

(2) Only where civilizations are of equal development and status can militarism be expunged from the list of essentials for survival. Nowhere in history have civilizations of equal status lived in proximity, unless we make the exception of Egypt and Babylonia.

(3) If the civilization you have created has not enough innate driving force and survival value of its own to transform barbaric peoples who intrude into it, and to assimilate them rapidly, then your civilization will break down by a process of steady barbarization. If you once admit the less civilized and their customs into your own highly developed structure, you will find them sapping its foundations, whittling it away, and leaving you nothing but a ruin.

In regard to this last, which to many will seem the most important in its application by analogy to modern conditions, Mr. Casson goes on to point out that while both the Mesopotamian peoples and the Egyptians admitted barbarians, it was the barbarians who vanished, and the same is true of Greece, but that though Rome admitted barbarians early, in course of time it was the Romans who were barbarized. Rome, he says, fell to an internal assault, which was an assault on the spirit as well as on the structure of Roman life, and the fabric fell an easy prey to the direct attack of still more barbarous barbarians. In support, Mr. Casson instances the evidence of recent archæological excavation in Britain, in which it has been shown how Roman villas were used as squatting places by the barbarous successors of the Romans on such sites. "You must deal with barbarians spiritually as well as physically," he says, "and convey to them that your civilization has qualities which they can envy and emulate, as well as wealth they can loot." Contrast the survival value of Greece. The Greeks absorbed foreign blood without losing their Greek character; and their invention, the *polis*, had not only a prodigious attraction as a mode of life to barbarians of all kinds, but also it carried Hellenism from Greece to the Indus. The Greeks saw that you must present to a people of a lower order of development something which will attract them to you, not with the desire to take your surplus wealth, but to emulate your mode of life.

"Such reflections," concludes Mr. Casson, "on the breaks and pauses in the course of civilization have some value for those who argue by analogy. . . . We should pocket our pride and glance at some of our past failures. For they are chastening to those who indulge in that greatest weakness of the civilized—complacency."

INSECTS IN THE UPPER AIR

BY DR. A. D. IMMS, F.R.S.

THE investigation of insects in the upper air has so far been conducted on a very limited scale. Probably the first attempt to collect insects from such an environment was that made by E. P. Felt, in the United States in 1926, who used a special kind of trap attached to the lower wings of an aeroplane. Since that year, several experimental attempts have been made to explore the insects and other arthropods of the upper air. Thus in 1931, 1932 and 1933 more extended flights by aeroplanes, with insect traps attached, were made in the United States.

The first European entomologist to attempt this line of investigation was L. Berland who, in 1934, used an aeroplane with specially devised nets attached to the wings and controlled from the cockpit. Many flights were made and all were in the vicinity of Paris. Very similar methods have also been used in Asia Minor and at Oran in Algeria. In 1937, J. A. Freeman made collections of insects in the upper air by using kites along the Great Lakes in Canada.

Between 1932 and 1935 Freeman, working in England in conjunction with A. C. Hardy, made a study of insect drift, using nets attached to 300 ft. masts of a wireless station. Specially constructed kites enabling samples to be obtained from given altitudes were also used. In 1938, A. C. Hardy and R. S. Milne published a detailed account of aerial tow-netting from kites with closeable nets attached.

The most extensive investigation of insects in the upper air is that described by P. A. Glick in Technical Bulletin No. 673 (May, 1939) of the U.S. Department of Agriculture. Under the title of "The Distribution of Insects, Spiders and Mites in the Air", a detailed account of the work, running to 150 pages, is given. The collecting was done during the five-year period 1926–1931, and special kinds of trap fitted to the wings of diverse types of aeroplane were employed. It appears that more than 1,300 flights were made at Tallulah (La.) and 44 flights in Mexico. More than 30,000 insects and spiders were taken at altitudes ranging from 20 ft. to 15,000 ft. and were most abundantly captured in the month of May. Eighteen orders of insects together with arachnids were represented. In the Tallulah collections there were more than 700 species belonging to more than 200 families. The order Diptera was the most abundant and was represented by nearly three times as many specimens as in any other order: Coleoptera followed next as regards numbers taken.

The highest altitude at which insects were captured was 14,000 feet and, as a general rule, their frequency of capture was in inverse ratio to the altitude. Among individual orders of insects, only 21 specimens of dragonflies were collected, and the author states that this is due to their rapid flight and their ability to avoid the oncoming aeroplane. He records having observed Odonata (probably *Anax junius*) keeping up with, and sometimes even flying ahead of, an aeroplane that was travelling at 90 miles or more per hour. Homoptera were captured at almost every altitude up to 14,000 feet. More than half of the Coleoptera taken belonged to the families Carabidæ, Staphylinidæ, Chrysomelidæ and Curculionidæ or, in other words, to the largest groups of these insects. Altogether 4,420 specimens belonging to 191 genera of Coleoptera were captured in the traps and the maximum elevation was 11,000 ft. Lepidoptera (32 species) were not captured higher than 5,000 ft. Hymenoptera, represented by nearly 250 genera, were obtained at nearly all elevations up to 14,000 ft. Their dominant representatives belonged to the Parasitica and the ants. Of the Diptera the most abundant families represented were the Chloropidæ with 2,227 specimens and the Chironomidæ with 701 examples. Culicidæ were represented by 111 specimens belonging to seven genera.

Among apterous forms, 1,461 spiders were captured, one example occurring at 15,000 ft. A single example of *Pulex irritans* at 200 ft. is recorded. Numerous Apterygota are mentioned, besides wingless Hymenoptera, etc., and larvæ.

Among the various factors governing the distribution of insects in the upper air the size, weight and buoyancy of individual forms are discussed together with the influence of temperature, dew-point, barometric pressure, wind direction and velocity, convection, light intensity, etc. Of these, and other factors, temperature is regarded as the most important agency regulating the numbers of insects to be found in the air at any given time.

With the great number of aeroplanes now in regular use in the world, numerous ways are offered for insects to find shelter in these vehicles and so become carried from one territory to another. New means for the dispersal of dangerous insect pests are thus afforded. Air currents are also believed to be an important accessory factor in the distribution of the destructive pink bollworm in the United States. During the five years of flying to collect insects, many kinds of these creatures were found either in the cockpit, fuselage or cabin of the planes used, but no special collections were made.

OBITUARIES

General the Hon. C. G. Bruce, C.B.

BRIGADIER-GENERAL THE HON. C. G. BRUCE died on July 12 at the age of seventy-three years.

Charles Granville Bruce, born in 1866, was a son of the first Lord Aberdare. Probably no man since the time of the Schlagintweits had a wider knowledge of the Himalaya than Bruce. No one ever had so intimate a knowledge of so many of its peoples. Bruce's climbing experience extended from the Safed Koh to Sikhim. He was with Conway in his notable expedition to the Karakorum, and with Mummery and Collie in the first attempt on Nanga Parbat. The snows of Khagan and Kulu were his happy hunting grounds. In 1907, the jubilee year of the Alpine Club, he nearly arranged the first exploration of Mount Everest; but at the last moment the plan was vetoed in London by John Morley, who feared Russian suspicion. Again in 1910 he got leave from the late Maharaja to explore Everest from the Nepalese side; but at the last moment this had to be given up for fear of arousing religious hostility.

By profession a soldier, Bruce was an acknowledged master in the difficult technique of fighting on the North-West Frontier. His influence with his own Gurkhas was remarkable, and his greatest contribution to mountaineering came through his wide knowledge of the tribes of the Himalaya. He was the first to use trained Gurkhas for serious mountain work. He started the Baltis of Kashmir and the Bhotias of Garhwal on the upward path, a lead which Kellas ably followed. But his great discovery was the value of the Sherpa, a Tibetan tribe long settled in Nepal. These, with their purer Tibetan cousins, have been the mainstay of every Himalayan expedition of recent years. The cause of his success was his sympathy with and knowledge of the languages and habits of these very varied peoples.

In 1923 Bruce was elected president of the Alpine Club. In 1915 he was awarded the Gill Memorial Prize and in 1925 the Founder's Medal of the Royal Geographical Society. But it was the adventure, not scientific interests, which absorbed him during his climbing holidays and longer expeditions. Of the latter, the Everest expedition of 1922 stands out. He made an ideal leader. Yet it is as a companion, the perfect one, that I most remember him, especially with Arnold Mumm and myself in Garhwal in 1907. He was the most invariably considerate, and pleasant, and uncomplaining companion it is possible to imagine. Not even the injured knee which deprived him of climbing Trisul with his devoted Subadar Kharbir Burathoki drew one word of disappointment or complaint from him. Bruce's name became a household word: but only his friends knew his real worth.

T. G. LONGSTAFF.

Prof. Archibald Young

PROF. ARCHIBALD YOUNG, who died in Glasgow on July 24 at the age of sixty-five years, had held the regius professorship of surgery in the University of Glasgow since 1924, when he succeeded Sir William Macewen. He had come under the influence of his predecessor, and this partly accounted for his leaning towards the surgery of the nervous system, to which he had regularly contributed since his service in the South African War. Moreover, this choice of speciality was natural in one whose clinical inclinations were coloured by the minutest examinations of clinical cases.

Prof. Young was at his best in dealing with conditions in which careful attention to the smallest details was essential for diagnosis and treatment, and to this characteristic may be attributed his success in dealing with fractures, with lesions of peripheral nerves, and with affections of the sympathetic nervous system. For many years his health was indifferent, and his work was carried on often in discomfort and not infrequently in pain; and it is a sad reflection that his last major contribution to surgical literature was a translation of Prof. Leriche's monograph on pain.

A man of the highest integrity and professional ideals, and of uncompromising opinions, Prof. Young instilled into all his students his example of steadfast devotion to duty. J. R. LEARMONTH.

WE regret to announce the following deaths:

Dr. W. C. Mansfield, geologist of the U.S. Geological Survey, on July 24, aged sixty-five years.

Dr. A. H. Trow, formerly principal of the University College of South Wales and Monmouthshire, professor of botany in the College during 1905–18, on August 26.

NEWS AND VIEWS

Science and the National Ideal

THE world stands on the brink of the abyss. Before these words appear in print, it may have taken the plunge; and ten million men will already have entered on the initial phase of a struggle, of which none can foresee the end, except it be in disaster. The efforts of those, who during the last twenty years have striven to reconstruct a civilization shaken to its foundations by the war of 1914–18, have been frustrated by the incompatibility of their aims with the exclusive methods of national regeneration. In all the antagonisms of recent years, the voice of science, except where throttled by the political partisan, has been steadfast in support of freedom of thought and toleration—to those of this way of thinking, essentials of social and intellectual advance, but now threatened root and branch by the aggressions of a totalitarian nationalism.

SIR ARTHUR KEITH (*Sunday Times*, August 27), while admitting the close kinship of exclusive nationalism with the tribalism of the barbaric Dark Ages, sees in its spirit the mechanism of progressive development, and contrasts it with a cosmopolitanism which is lacking in force and colour. But in this contrast is he not guilty of a false antithesis, to which he is led by a too crude and outmoded interpretation of the Darwinian's force of natural selection? In the history of civilization, the struggle for existence has been resolved from one of brute force into a struggle for survival among ideas. Too true that often advancement has come about, and the world being what it is, must still at times come about by the aid of the driving force of the national idea. But more and more the struggle loses the character of national rivalry and becomes one in which we move, slowly it may be, towards a world order, which is not merely an undifferentiated cosmopolitan universalism, but an order to which each group, be it people, nation, or empire, by the development of its traditional culture to its highest power, may contribute something towards the common good and advancement of mankind as a whole. This is the faith and the ideal of a nationalism to which science must cling fast at all costs.

Education to Meet the Challenge to Democracy

SOME two thousand representatives of parents and teachers in the United States recently met at Cincinnati to discuss "The Purposes of Education in American Democracy" under the four heads: self-realization, human relationships, economic efficiency and civic responsibility. The proceedings culminated with a remarkable address by the president of the University of Wisconsin. American education, he said, entrusted as it has been to local inspiration, leadership and control, with emphasis on individual rights and individual liberty and but little sense of national responsibility, has for generations taught values which no longer conduce to a proper understanding of a world infested everywhere by a highly organized and efficient system of vilification and ridicule of the whole theory and method of democracy. The dictators are cultivating a common interest and a new goal; telling the masses that to save one's life one must lose it in devotion to a common social ideal. How can this be countered in a society split into groups which are at war with each other on political, social and economic fronts? Only by engendering an overriding devotion to what it wholeheartedly believes to be a worthier common social ideal. "Only a dynamic democracy can cope with a fact-facing fascism." The need is urgent. Only a conscious educational programme can produce the requisite sense of common purpose and common sacrifice, active, steady and constant. It "calls first of all for an understanding of democracy as a way of life and a nourishing of the underlying values upon which society depends for its existence. . . . Education must face this issue or lose its liberty and its opportunity". The address is reported in the July issue of *School Life*, the official organ of the Office of Education.

Use and Misuse of Science

IN his presidential address "The Use and Misuse of Science" to the Royal Society of New South Wales, which has been reprinted in part from the *Journal and Proceedings* of the Society, Prof. J. C. Earl points out that control over Nature involves not merely the knowledge that in certain circumstances a known natural phenomenon will occur, but also the ability to arrange the stage so that the occurrence takes place when and where we will. Knowledge may be power, but it remains inactive until a conscious effort is made to use it. We can use the power we have constructively or destructively, and this responsibility cannot be regarded lightly. Our conduct must be determined by some motive and the moral issue cannot be evaded. Discussing the use of science, Prof. Earl termed research associated with the use rather than the extension of knowledge, secondary scientific research, in contrast to primary scientific research, which is concerned with the extension of knowledge as such. The latter he considered an essential duty of a university, the discharge of which would foster its other duty of maintaining cultural traditions. He urged that the tendency to foster secondary rather than primary research in the universities of Australia with the resources now available was dangerous and that the claims of the latter required more energetic support from within and without. In urging this larger and keener interest in fundamental work, Prof. Earl did not suggest, however, that secondary scientific work was less important, and he referred to the need for scientific work in Australia on Australian products.

Mental Disease and War

IN a recent essay (*Hibbert J.*, 37, 513; 1939) on mental disease as a factor in the causation of war, Dr. Olof Kinberg, professor of forensic psychiatry at the University of Stockholm, remarks that though it is growing increasingly clear that war as a means of solving social problems is utterly futile, for the remedy is worse than the disease, many large countries are seeking to imbue even their children with an admiration for war and to do all they can to represent it as the most glorious exposition of national greatness, while other countries are making every possible effort to avoid war, though they are compelled to build up enormous armaments. Prof. Kinberg discusses some of the psychological features of modern society which may help to explain this paradoxical state of affairs. He points out that in order to mould public opinion the ruler must transform private citizens into a psychological mass and keep them in that condition for a considerable time. The production of this mass is brought about by the Press and the radio being in the hands of the Government, the formation of a bulwark against criticism and the persecution and destruction of anyone who dares to entertain different opinions.

PROF. KINBERG directs attention to the likeness between the qualities of the national mass and the paranoid personality which is characterized by touchiness, egoism, quarrelsomeness, inability to judge its own affairs impartially and a conceit and arrogance which sometimes takes the form of megalomania. At the same time the mass adopts towards its leader, however shabby and obscure his past may be, an attitude of servile submission which contains a strong infusion of magic and mysticism. A continuous interaction takes place between the national mass, whose passions are kept at boiling point, and the leader, who has himself shown from the onset abnormal psychical features of a paranoid character. Such a state of affairs, according to Prof. Kinberg, has been exemplified from the French revolution down to the revolutions of the present day.

Eiderdown Industry and Protection of Eider-Ducks

THE numerous islands which border the north coast of the Gulf of St. Lawrence have long been a breeding ground of eiderducks. But it is only since 1933 that a supervised industry in the collecting and marketing of eiderdown has been established. During the past six years the export of cleaned eiderdown has increased five-fold, and the recognition of the value of the birds has led to active protection and encouragement of an increasing stock of nesting ducks. Where the eiderdown industry has been established severe penalties are enforced for their destruction or molestation. The collection of the down, it is reported by the Office of the High Commissioner for Canada, does not interfere with the regular hatching of the eggs, and as a result of this and of protection the colonies of eiders have been steadily increasing in numbers. For the purpose of eiderdown production, residents of the Gulf-shore area now lease from the Province of Quebec suitable coastal islands at a nominal rental for a period of five years, and each lessee is supplied with a permit under the Migratory Birds Convention Act authorizing him to collect, possess and sell eiderdown taken from the nests in his leased area. We trust that a close watch will be kept upon this new industry and that definite counts will be made by scientific observers at periodic intervals to test the effect of the trade upon the number of birds. The conditions of the leases granted to the down collectors are unknown to us, but it is hoped that some provision is made to check what might easily develop into ruthless destruction at the close of a period of lease, if the lessee suspected that renewal might not be granted.

Re-organization of the Cotton Industry

THE Cotton Industry (Reorganization) Act, which has since reached the Statute Book, is the subject of a further broadsheet issued by P E P (Political and Economic Planning). The Cotton Industry Board to be appointed by the Board of Trade will be representative of all sections of the industry in addition to having three independent whole-time members, including the chairman, with special knowledge of the industry. The Board will appoint, partly from among its own members, a special Export Development Committee, which will have the particular duty of making recommendations regarding the export trade. Cotton and rayon interests will be equally represented on the Committee and the other principal bodies in the industry will be the Cotton Industry Advisory Committee, charged with examination of the sectional schemes, and the Representative Advisory Council. Provision is also made for the establishment of a separate Rayon Industry Committee. Producers are compelled and merchants permitted to register with the Cotton Industry Board, but merchants will only be registered if they agree to abide by the contracts prescribed in sectional price schemes. Sectional schemes, which to become legally binding must be supported in a poll by the majority of the section concerned and approved by the Board, may relate to the elimination or reduction of redundant plant or to the fixing of prices. The broadsheet emphasizes the importance of marketing policy, the need for market research, the urgency of establishing central marketing arrangements, the necessity of a more enlightened labour policy than that which has short-sightedly sought exemptions from the Factories Act which reduced the juvenile working week from 48 to 44 hours, as well as the importance of implementing the permissive clause of the Act which allows the compensation of operatives displaced by redundancy schemes. Only long-term measures of this character can overcome the operatives' real and natural fear of technical change and eliminate the labour troubles which have contributed to the industry's difficulties.

Mr. W. Gavin, C.B.E.

IN further development of the organization which would be set up by the Government in the event of war to bring about an increase in food production in Great Britain, Mr. W. Gavin has been appointed agricultural adviser designate to the Minister of Agriculture and Fisheries. Mr. W. Gavin has already served in the Ministry of Agriculture, having been appointed in 1916 to act as assistant to the late Hon. E. G. Strutt, who was agricultural adviser throughout the war of 1914–18. Mr. Gavin afterwards became secretary and deputy director of the Army Cattle Committee, director of flax production and director of land reclamation. He is now the agricultural adviser to Imperial Chemical Industries, Ltd., a director of Strutt and Parker Farms, Ltd., a director of the Agricultural Mortgage Corporation, a member of council of the National Institute of Agricultural Botany, a trustee of the Lord Wandsworth Agricultural College, and an 'appointed' member of the executive of the Potato Marketing Board.

Bernhard Naunyn (1839–1925)

BERNHARD NAUNYN, an eminent German physician and experimental pathologist, was born on September 2, 1939, in Berlin, where he studied medicine under Lieberkühn, Reichert and Frerichs. He qualified in 1862, and after acting as clinical assistant to Frerichs for some years, became successively professor of medicine at Dorpat (1869–71), Bern (1871), Königsberg (1872–1888) and Strassburg (1888–1905). He was the author of two medical classics, the first on cholelithiasis (1892), which was translated into English by A. E. Garrod for the New Sydenham Society's publications (1896), and the second on diabetes mellitus (1898). He also wrote important articles on cerebral compression, the problem of fever, coagulation of the blood, gastric fermentation, cirrhosis of the liver, disorders of speech and syphilitic disease of the nervous system. Considerable historical interest is attached to his papers on "The Development of Internal Medicine in the Nineteenth Century", "The Berlin School 50 Years Ago" (1908); and his autobiography entitled "Erinnerungen, Gedanken und Meinungen". In 1872 he founded, in conjunction with Schmiedeberg, the *Archiv für experimentelle Pathologie und Pharmakologie*, and in 1896, with the surgeon Mickulicz, the *Mittheilungen aus den Grenzgebieten der Medizin und Chirurgie*. Naunyn had many pupils who attained distinction, such as Eichhorst, Minkowski, Schreiber, Stadelmann, Umber and Weintraud. He remained active in his retirement at Baden-Baden until shortly before his death, which took place on July 26, 1925.

Gift of Sutton Hoo Antiquities to the Nation

ALL anxiety, which has been not inconsiderable, as to the future of the antiquities from the Sutton Hoo Anglo-Saxon royal ship-burial has been allayed by the announcement made by the Trustees of the British Museum (Bloomsbury) that Mrs. E. M. Pretty, declared their owner by the verdict of the Coroner's inquest of August 14 (see NATURE of August 19, p. 318), has generously presented them to the Museum. The gift is subject to a condition that they shall be exhibited in due course on loan for a period in the Borough Museum of Ipswich. The gift comprises articles in gold, gems, and enamel, silver, bronze, iron, stone, wood, leather and textile fabrics—everything, in fact, which was found in the ship-burial on her estate at Sutton Hoo. Thus the relics from a find, which archæologically is the most important of its kind made in Great Britain, and the most valuable of its period made anywhere, not only become the property of the nation, but also will be preserved together as a whole. Had the collection been dispersed, as was feared possible, the discovery would have lost much of its unique value for cultural studies, and as tangible evidence for the whole complex of religious and social concepts, which inspired our Anglo-Saxon forbears in the seventh century of our era in their reactions to the demise of a chiefly head and representative of the community. Intrinsically valuable objects and jewels in gold, silver, and enamel, especially when found in such rich profusion, impress the popular imagination: they afford evidence of a highly developed æsthetic faculty and superb skill in technique; but it is the humbler objects with which they are associated, the personal and domestic articles of the less precious metals, the pottery, the wood, leather, stone and the textiles, which are the more eloquent for the student of the culture of the time. They are the raw material from which the archæologist interprets advance in civilization and the cultural history of the people as a whole.

EXCAVATIONS are still proceeding on the site in the hope of securing further evidence, which will throw light on certain points still obscure. It would appear to be beyond doubt from the completeness of the funeral furniture, the extensive equipment, domestic and personal, and the unexampled richness and excellence in workmanship of the jewellery and objects in precious metal, that this was the burial-place of a king or chiefly leader, which is to be assigned, on the evidence of the Merovingian coins, though themselves bearing no date, to about A.D. 640; but as yet no evidence of identification has been found. Such suggestions as have been made are purely speculative. It is further remarkable that no skeleton, or fragments thereof, or evidence of cremation, have been found. It has been suggested as possible that the burial mound may have been intended to confer the last rites on a leader whose body had been lost at sea. Should further relics accrue, presumably they will be added to the original gift, with a generosity worthy of the owner. The verdict of the Coroner's inquest, however, has given rise to some serious misgivings as to the possibilities to which a find of this value, and in such circumstances, is exposed. It has been suggested that drastic measures should be taken by legislation to ensure their reservation to the nation. It is probable that any such action would defeat its own end. The generous interpretation of compensation now accepted in application of the law of treasure trove, which ensures to the finder the full archæological value of a find, and the vigilance of the Office of Works, are adequate to meet ordinary contingencies, while any exceptional find, such as that at Sutton Hoo, is certain of the protection of a publicity which would be intolerant of anything in the nature of improper disposal.

A Museum of the Roman Wall: An Appeal

WHILE some, at least, of the advantages of an adequate display for relics from the Roman Wall must be obvious to every layman who gives the matter a thought, only an archæologist can appreciate to the full both the hindrances to Romano-British studies of the present arrangements, as well as the benefits which would follow from the appropriate grouping of the collections in premises dedicated to this sole purpose. Mr. Ian A. Richmond, lecturer in Romano-British archæology in the University of Durham, in a review in *The Times* of August 29 of the present position, touches upon both aspects of the matter in putting forward a plea for better accommodation for at least some of the collections under the custody of the University of Durham. At present the relics from the Wall are divided between three principal museums, the Blackgate at Newcastle-upon-Tyne, Tullie House at Carlisle, and Chesters on the Wall itself. These museums are both overcrowded and ill-adapted to the requirements of modern display. In particular, the Blackgate, the medieval gateway of the Castle, is the most urgent problem. Once a debtors' prison, it is dark and gloomy, yet it contains the collections of the Society of Antiquaries of Newcastle-upon-Tyne, which now have been in existence for more than a century and are the most important source of information on the Wall and its area.

So strongly did the needs of the situation and the claims of Hadrian's Wall as "one of the universally famous monuments of our island" appeal to the Standing Commission on Museums and Galleries that it was from this body that the suggestion came that the responsibility of a museum of the Roman Wall should devolve upon the University of Durham; and following upon an expression of willingness by the Council of the Society of Antiquaries to transfer the custody of its collections to the University, and an appeal to the public by Lord Eustace Percy, as representing the University, for funds to erect such a museum, the University Grants Commission has generously made an offer of £5,000 towards the cost of the building, provided the balance of £15,000 required is raised within two years. Mr. Richmond goes on to point to a number of directions in which study of Romano-British culture is hampered through lack of adequate and appropriate display of the material.

Gloucester Museum

REFERENCE was made recently in the columns of NATURE (July 15, p. 91) to the origin of certain of the provincial museums as centres of intellectual and social exchange in days of less easy transport and communication. An example of a museum originating in this manner and of the function it is now able to fulfil in municipal life is afforded by the Public Museum of the City of Gloucester. This museum was founded in 1859 by members of the Gloucester Literary and Scientific Association (now dissolved) and the Cotteswold Naturalists Field Club. The collections were housed originally in two rooms lent by Mr. Sydney Dobell, but were removed to the Art School in 1872, and finally transferred to their present home in the Price Memorial Hall in 1900, having been handed over to the Corporation by deed in 1896. A scheme of reorganization has been completed recently and the occasion marked by the issue of a "Short Guide to the Collections", which includes, in addition to the collections in the Public Museum, those of the Folk Museum in Bishop Hooper's Lodgings, opened by Dr. R. E. Mortimer Wheeler in 1935. The Public Museum covers both natural science and archæology; and specimens are available for detailed examination by students and research workers in a reference room set aside for the purpose. The archæological specimens are in the main of local derivation, and are arranged to illustrate the development of the material culture of early man in the local environment down to Saxon times. Historical relics later than the Norman Conquest are to be found in the Folk Museum, which illustrates the medieval and later economic and social life of the city and surrounding country in agriculture, trades—Gloucester is famous for its early iron-working—and the home. A special exhibit arranged for the jubilee conference of the Museums Association at Cheltenham in July had as its most prominent exhibit a selection of the local horn industry, which has existed in Gloucester since medieval times and still survives in one small factory.

Indian Association for the Cultivation of Science

THE annual report of the Committee of Management of the Indian Association for the Cultivation of Science for the year 1938 records a membership of 128 at the end of the year (Calcutta: Indian Association for the Cultivation of Science, 1939). Financial stringency has limited the purchase of reference books and periodicals for the library and also that of scientific apparatus, and for the same reason the Government of India has been unable to restore the ten per cent cut in the annual grant of 20,000 rupees for the year 1938-39. Appendixes include lists of periodicals available in the library and of books purchased as well as an account of research work carried out in the laboratories of the Association. An arrangement has been devised for magnetic measurements, at low temperatures in the range obtainable with liquid air, on typical paramagnetic salts of the rare earth and the iron group. Magnetic measurements on rhodochrosite, $MnCO_3$, indicate that this crystal should prove a more suitable substance than the hydrated sulphates and selenates of manganese for use as the medium for the production of very low temperatures by the demagnetization method. Other studies have included the magnetic anisotropy of hydrated gadolinium sulphate, crystalline fields in rare earth salts, magnetic studies in relation to valency problems and to crystal structure, magnetic studies on organic crystals of the aromatic class, and optical studies of the chrysene molecule. Other work has been concerned with the absorption spectra of arsenic and antimony sulphides and of the sulphur molecule.

Adult Education in Household Science

HOME-LIFE problems have become, under the impact of social and economic changes, increasingly complex and baffling, and among expedients employed in the United States for coping with the situation is the promotion of adult classes for home economics. Such classes are becoming increasingly important, and the Office of Education has issued a stimulating and helpful guide entitled "Homemaking Education Programs for Adults" (Washington, D.C.: Government Printing Office. Pp. 126. 15 cents). A detailed discussion of principles and methods of instruction appropriate for communities of different types and the preparation of teachers and leaders is followed by illustrations drawn from various parts of the United States. As an example of the scope of the work of the classes, here is a list of headings taken from a Kansas leaflet for use by itinerant teachers: food for the family, clothing, child-care and development, home-management, care of the sick, shopping, home-planning and furnishing, hospitality in the home. The extent and character of the existing provision for such classes vary widely in different parts of the country, but the discussion reveals the existence of an increasing emphasis in American theory and practice on the necessity for "the extension of educational activities beyond the confines of the school building into the community", involving acceptance by the public educational authorities of responsibility for provision of nursery schools and adult classes. The bulletin contains much that should interest household science schools, organizers of adult education and women's institutes.

Health Organisation of the League of Nations

THE annual report of the Health Organisation is contained in its recently issued *Bulletin* (8, Nos. 1–2, Allen and Unwin, Museum Street, W.C.1. 5s.). Prevention and treatment of malaria, cancer, leprosy, nutrition, housing and physical education, biological standardization and drug traffic are some of the subjects that are covered by the activities of the League's Health Organisation. A considerable report on rural housing and planning is contributed by M. Vignerot (France). The last article, of 260 pages, is a survey by Dr. Walch-Sorgdrager of Leptospiroses, diseases of man and animals caused by infection with minute spirilliform micro-organisms, which include infectious jaundice or Weil's disease of man and infectious jaundice of dogs. A recently differentiated epidemic disease of man, 'mud fever', is fully described. It occurs in regions of the Danube, Elbe and Oder which are liable to floods, though is not necessarily connected with flooded districts, and is caused by a species of Leptospira, *L. grippotyphosa*. The disease is an acute and severe febrile condition, but is never fatal. The natural habitat of this microbe is uncertain, as is also the problem of transmission to man. A bibliography of 70 pages completes this important article. A review designed to show how the Health Organisation functions, entitled "World Health and the League", is also issued by the League (Messrs. Allen and Unwin. 6d.).

Birth Customs in East Anglia

IN the June issue of *Folk-Lore*, Miss Barbara Newman and Mr. Leslie Newman record the result of a questionnaire sent to a large number of nurses in Norfolk, Suffolk, Essex and Cambridgeshire for information on husband's 'labour pains' and husband's pains other than labour, such as sympathetic morning sickness and toothache, the use of herbal remedies to ensure easy labour or to quicken labour, and customs connected with the placenta, umbilical cord and caul. Nearly all the midwives agreed that 'husband's pains' were quite usual. In one case a medical man had himself suffered therefrom, and had no doubt that in cases which had come under his observation the pains were both genuine and severe. As regards the prevalence of 'husband's toothache', it was reported that at a town council

NATURE

SUPPLEMENT

Vol. 144 SATURDAY, SEPTEMBER 2, 1939 No. 3644

THE WESTERN ISLES THROUGH THE MISTS OF AGES

By Sir Albert C. Seward, F.R.S., President of the British Association[*]

Introductory

TWENTY-SEVEN years ago, when the British Association met for the second time in Dundee, Sir Edward Schäfer chose as the subject of his presidential address, "The Nature, Origin, and Maintenance of Life"; he discussed problems that will long continue to exercise the ingenuity and stimulate the imagination of biologists and chemists. A theme such as his is far beyond my reach. Seventy-two years ago, the Association met for the first time in this city. The Duke of Buccleuch occupied the presidential chair, and the opening words of his address are applicable to one who now finds himself in this privileged position The Duke said: "No man has a title to state that he is unworthy of the post he is called on to fill, whatever may be his private feelings as to his fitness for the post. To state that he is unworthy to be there placed is not only a disparagement to himself, but is no great compliment to those who thought him worthy of being so placed".

This, in my opinion, is not an occasion on which it is desirable to follow the easier course and address oneself in technical language to fellow-workers in the pursuit of natural knowledge. The position which it is my great privilege to occupy affords a rare opportuntiy of talking to a large and, I venture to hope, a sympathetic audience, including some at least who are repelled by the jargon of specialists. My intention is to speak in ordinary language on a subject of which I know enough to realize how little that knowledge is, and briefly to describe an example of the way in which, within one small patch of an illimitable field, a student asks questions of Nature and does his best to interpret the answers.

An Excursion into the Past

I invite my audience to accompany me on an excursion of a kind which has substantially contributed to the enjoyment and enrichment of my own life, an excursion into a world that knew not man, with the object of deciphering from such records as we find in the rocks a few pages of the story-book of the earth. Each one of us can say with Shakespeare's soothsayer:

> "In Nature's infinite book of secrecy
> A little I can read."

As that great Scotsman, Hugh Miller, wrote nearly a century ago: "We find the present incomplete without the past—the recent without the extinct". To reinforce his own opinion he quoted Samuel Johnson: "Whatever makes the past, the distant, or the future predominate over the present advances us in the dignity of thinking beings". We shall try to reconstruct a small part of an ancient land, a remnant of which is now called Scotland, and envisage a scene at a stage in the history of the earth separated from the present by at least sixty million years, a stretch of time difficult for us who have been called "the afterthoughts of creation" fully to appreciate. When we substitute geological standards for the modest time-scale of the human period and remember that the earliest chapters of the world's history are recorded in rocks at least two thousand million years old, sixty million years dwindle to comparative insignificance. All that it is possible to do is to lift a corner of the veil separating us from the world as it was and view through dimly illuminated vistas the forests and undergrowth on an ancient continent that is now represented by a few widely scattered, dismembered pieces.

---

[*] Presidential address delivered at Dundee on August 30.

THE HISTORY OF PLANT LIFE

The history of plant life in the sea and on land is a branch of natural knowledge not unworthy of consideration by us human beings who owe our existence to the vegetable kingdom. Green plants in one vital sense are our superiors: from air and water they build up the complex organic substances necessary to our life, a feat beyond man's power. As members of a subject race we should be interested in endeavouring to unravel the history of the plant kingdom—in trying to trace the origin and relations of the several classes and groups as defined by botanists. The documents that are the sources of the botanical historian are contained in the earth's crust: as a preliminary it is worth while to ask ourselves of what these documents consist; how they came to be preserved in the rocks.

In order to bring to life the past we must take the present for our guide: "speak to the earth, and it shall teach thee". There is no reason to think of Nature's methods as other than continuous. If we stand by the bank of a river flowing past tree-covered slopes, we see on the sand and mud by the edge of the channel or floating on the stream, leaves, twigs, and seeds that are random samples of vegetation scattered by wind or shed from overhanging boughs, debris swept along with off-scourings from the rocks to be carried eventually to a delta or an estuary where the water-borne material comes to rest. Beds of old sands and mud, with included fragments of contemporary trees and other plants, exposed on the faces of cliffs and ravines, are layers of sediment that have been raised to a higher level. In addition to leaves, twigs and other scraps easy to see on the split surface of sandstone or shale, sediments of former ages, especially such as are peaty, occasionally furnish another valuable source of information invisible to the unaided eye. Minute grains of pollen may be carried by wind to places where conditions are favourable for their preservation: fortunately the grains, or at least most of them, are protected by highly resistant coats and retain almost for all time their characteristic form and surface-sculpturing. With scarcely any exception, it is possible for a specialist, by comparative microscopical examination of fresh material, to assign fossil pollen-grains to their generic and occasionally their specific position in the plant kingdom.

There is another natural agency to which students of extinct plants are not infrequently indebted — the formation of rocks by volcanic action. From time to time, volcanoes that have long been dormant eject clouds of ash: these, with streams of lava poured over the rim of a crater, spread havoc among trees and shrubs that had colonized precarious sites during a peaceful interlude. Vulcanicity is not only destructive: paradoxical as it may seem, forces inimical to life have contributed to the reconstruction of life which they destroyed. Scotland is exceptionally rich in botanical treasures that are legacies from ages of fire, and indeed the fossil plants with which we are concerned here owe their preservation to volcanic forces.

The following botanical retrospect is based mainly on results obtained during the last two or three years, but not yet published, by the joint efforts of Mr. W. N. Edwards, keeper of geology in the British Museum, Dr. J. B. Simpson of the Geological Survey, and myself.

RECONSTRUCTION OF A FOREST SCENE

A. *The geological background:*

(i) *Prolonged and intermittent volcanic activity*

In order to present in true perspective the scene which it is my aim to bring to life, it will be helpful to visualize the physical features in north-western Europe some thousands of years antecedent to the phase of geological history chosen for closer examination. The chalk downs of England and part of the cliffs on the Antrim coast of Ireland are made of upraised calcareous material that was once a soft white ooze on the floor of a clear sea, a sea which had swept slowly and irresistibly over an enormous stretch of land, embracing the greater part of England, northern Ireland and part of the region that is now western Scotland. With the uplifting of the chalky ooze from the ocean bed and the gradual recession of the waters a new land was born; a new chapter was inaugurated in the history of the earth.

Following the great upheaval, as a consequential phenomenon, subterranean forces that had long been quiescent gained the upper hand: floods of semi-molten rock from deeply hidden reservoirs surged as a fiery deluge over the chalk downs, and over other and older rocks, converting thousands of square miles into barren lava-fields, extending over an area, not less than 2,000 miles from south to north, which reached far beyond the Arctic Circle.

This unprecedented manifestation of volcanic energy, which is by no means confined to Europe and the arctic regions, but recorded on an equally titanic scale in the peninsula of India and elsewhere, is one of the wonders of geology; it is convincing evidence that the earth after the lapse of many hundred million years had not lost her youth; there was no sign of senescence. During the period we are considering, most of Britain was land: we know that at a slightly later date a broad sea lay over the whole of what is now southern England. Travellers in the tube-railway in the London district may perhaps derive pleasure from the knowledge that they are being conveyed through a stiff clay upraised from the floor of that ancient sea. As an appropriate designation for the great northern land an American geologist suggested the name Thulean continent or province (see map, p. 417). In the early days of the period called by geologists the Tertiary era, the greater part of the Thulean province was covered with sheets of sombre-coloured lava in nearly horizontal layers, products of a series of outbursts from deep fissures rent in the earth's crust under the compelling strain of subterranean forces, and from localized volcanic centres of eruption. The columnar basalts of the Giant's Causeway, the columns of the 'cathedral of the sea' at Fingal's Cave, the basalts of Mull, Skye, Canna, Eigg, and other Western Isles, weathered into step-like terraces, which form a characteristic feature of Hebridean cliffs, the flat-topped McLeod's Tables of Skye (1,600 ft.), precisely similar basaltic platforms on the hills of Disko Island and the mainland of western and eastern Greenland—all these are parts of one stupendous whole, a plateau covering half a million square miles, that was once the Thulean continent. The widespread lava-flows represent one phase of volcanic activity in an age of exceptional unrest.

Another phase is illustrated by more coarsely crystalline rocks such as those of the dark Cuillin hills of Skye: they were not poured out as lava-streams over the land, but were forced upwards as great dome-like masses from a deeply seated subterranean source and, as their coarser texture proves, slowly cooled under the pressure of a thick superincumbent load: the comparatively large size of the crystals indicates gradual solidification from a molten mass.

These two phases of prolonged rock-building help us to appreciate the immensity of geological time. Describing the lava-flows of Mull, Sir Archibald Geikie wrote: "On Ben More we can walk over each bed of basalt from the sea-level to the mountain top, a height of 3,169 ft." The basaltic lavas we see in the cliffs of Mull, and many other islands are but a part of the original pile: those that remain furnish an impressive example of rock construction which must have extended over an enormous period of time. The second phase, on the other hand, is an equally impressive example of rock destruction as a measure of geological time. We see the jagged peaks of mountains rising to a height of 3,000 ft. above sea-level which, at no distant date as earth history is reckoned, were buried under a considerable thickness of younger rocks that have been utterly destroyed by the ceaseless operation of denuding agents.

The world to our limited vision appears to be almost static; the mountains we have been accustomed to think of as symbols of eternity, seen through geological spectacles, take their place as episodes in a series of events which have moulded the changing features of the earth's face. The rocky covering of the world viewed by geologists, "foreshortened in the tract of time", reveals itself as a dynamic, mobile crust responding from age to age to constructive and destructive forces which have operated since the earth's early youth, following a still earlier stage when, in the imagery of the poet,

"This world was once a fluid haze of light."

(ii) *Plant-bearing sediments indicative of quiescent intervals*

So far the events chronicled in rocks of igneous origin have been spoken of as though there had been continuous outpourings of lava with occasional showers of ash and, in some districts, upwelling of molten material that remained hidden below the surface until in the course of time the covering rocks were removed by erosion. There is, however, clear proof that the extrusion of lava and other rocks was intermittent: intercalated among the lava-beds are layers of sedimentary material, hardened sand and mud, layers of coal, and beds of fine-grained limestone containing beautifully preserved leaves, a few fruits and other plant fragments, also rare examples of insect wings and shells. The richest plant-containing layers occur near the base of the pile of basaltic lavas on Ardtun Head, the low 'headland of the waves' near the south-western corner of Mull, the island on which from his home on Iona—which has been aptly named 'the light of the western world'—Saint Columba must often have gazed. Trees, shrubs, and other plants were able to colonize portions of the lava-field during the long pauses between recurrent outbursts of volcanic fires.

The association of sedimentary material with the basalts at Ardtun Head was noticed by Abraham Mills so long ago as 1790; but it was not until the middle of the nineteenth century that Mr. McQuarrie of Bunessan discovered the fossil plants, which were very briefly described by Prof. Edward Forbes in an appendix to an important paper by the Duke of Argyll published by the Geological Society of London in 1851. The Duke spoke of the leaves as having been shed "autumn after autumn into the smooth still waters of some shallow lake, on whose muddy bottom they were accumulated, one above the other, fully expanded and at perfect rest". By far the richest collection of fossils was made by Mr. Starkie Gardner rather more than fifty years ago, and partially described by him in a paper read to the Geological Society of London in 1887. Descriptions of several fossil plants from the Mull beds have also been published by Dr. T. Johnson. The main collection is now in the British Museum. Additional specimens have been obtained by other collectors in more recent years.

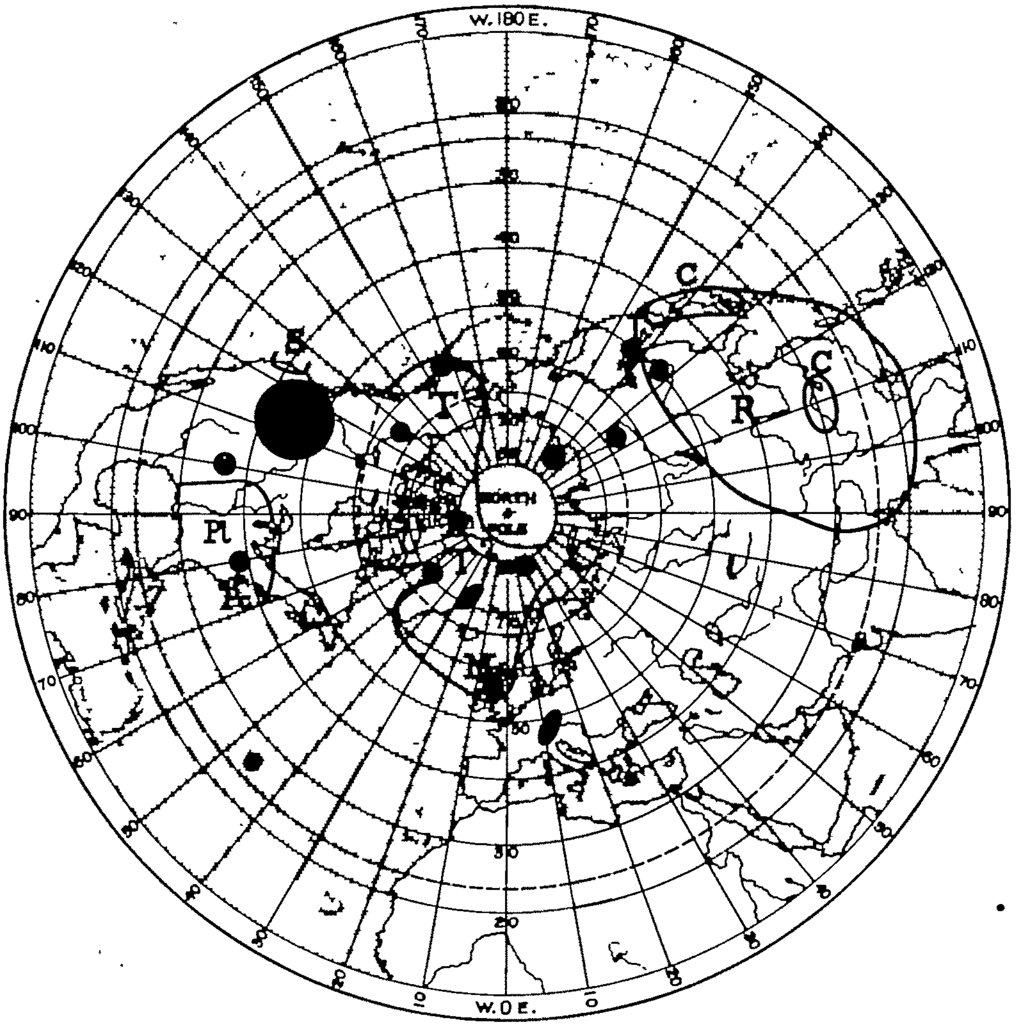
The work of deciphering the botanical records from Mull, Skye, and a few of the other islands is rendered mildly exciting by the danger of misinterpretation: fossil leaves, we are often reminded, are very uncertain guides—records left by Nature in a mischievous mood to mislead the unwary and over-confident student. Sir Joseph Hooker, in an address to the British Association at Norwich in 1868, spoke of fossil botany as "this most unreliable of sciences"; but he added by way of consolation—"the science has of late made sure and steady progress, and developed really grand results". One may cheerfully take the risk of being called an unscientific optimist by colleagues whose chief concern is with living plants. Botanists who confine their attention to recent plants have ample sources of information, not merely detached leaves but twigs bearing leaves, flowers, and fruits: it is natural, therefore, that they should tend to under-estimate the value of leaf-form and venation, often the only criteria available to the palæobotanist.

B. *The ancient flora of the Inner Hebrides.*

What then is it possible to say about the ancient flora of the Inner Hebrides without transgressing the limits of probability? We know very little of the smaller and simpler plants which lived under the shade of the forest trees or clung to the surface of stems where they were washed by trickling rills of rain-water. The three smallest plants which have left recognizable fragments are a fungus and two liverworts or, as they are often called, hepatics, a group allied to the mosses but of simpler construction. The fungus was found by Mr. Edwards several years ago on some detached leaves of a conifer from the Mull plant-beds; the manner of its discovery illustrates an interesting technique often employed with success by students of fossil plants. In many instances leaves preserved on shale are covered with a very thin, black coaly film produced as the result of chemical change in the plant tissues after death. It is often possible, by detaching a piece of the film and treating it with certain clearing agents, to remove the carbonaceous matter and obtain a sample of the surface skin of the leaf that is brown in colour, transparent, and suitable for microscopical examination. After treatment, the Mull leaves showed some minute dark spots on the surface film, and these on magnification were found to be circular disks made of rows of radially disposed cells. The disks were identified as organs of a fungus closely resembling reproductive structures of a living genus Phragmothyrium, a fungus now mainly tropical: the occurrence in Mull of a nearly allied form is, however, probably indicative of a moist rather than a tropical climate. One of the liverworts bears a close resemblance to a living species, *Pellia epiphylla*, which has a wide geographical distribution and is very common on damp earth in Britain; it has a flat green, forked body barely an inch in length. The other hepatic is a member of a different family, characterized by a slender thread-like stem bearing two rows of minute leaves; it bears a striking resemblance to some living species included in the order Jungermanniales.

These fragmentary remains of liverworts are worth mentioning because fossil examples of such plants are comparatively rare; also for a more important reason. A few years ago Prof. J. Walton of Glasgow published a description of some liverworts discovered for the first time in rocks containing remains of plants which grew in the forests of the Coal Age about 200 million years ago. The interesting fact is this:

the Palæozoic liverworts differ scarcely at all in the construction of the delicate plant-body from the much later forms from the Thulean continent : both are essentially modern and yet both are surprisingly ancient. We do not know much about the history of these plants, but it is clear that some liverworts persisted through a succession of geological periods with practically no modification of their simple design.



MAP OF THE NORTHERN HEMISPHERE ILLUSTRATING SOME OF THE SUBJECTS DEALT WITH.

C, C. The present geographical distribution of Cercidiphyllum, a Japanese and Chinese tree. Black patches mark localities and districts where fossil specimens of Cercidiphyllum have been found. Arctic and sub-arctic regions : Alaska, Mackenzie River, Grinnell Land and Ellesmere Land, West and East Greenland, Spitsbergen, New Siberian Islands, Lena River. Canada and the United States of America : several localities from British Columbia and California, and east of the Rocky Mountains in Montana, Wyoming, Oklahoma, etc. The oldest examples of Cercidiphyllum leaves are from early Cretaceous rocks in Maryland—the Potomac formation (*Pc*). Others are recorded from Europe—Mull, Switzerland, Bohemia, Silesia ; Eastern Asia ; Sakhalin Island and the Bureja River.

M. Mull and neighbouring islands.

Pl. The geographical distribution of the occidental plane.

R. Approximate boundary of the area within which are the present homes of the majority of trees and shrubs most closely related to extinct species of the Hebridean flora.

S. The present distribution of *Sequoia sempervirens* (redwood) and *Sequoia gigantea* (mammoth tree).

T. Hypothetical boundaries of the Thulean province.

The only fern so far discovered is very nearly related to the sensitive fern, *Onoclea sensibilis*, a familiar species in North America, ranging from Florida to Newfoundland and as far west as Saskatchewan ; it occurs also in northern China, Manchuria, Japan, and Corea: it has what is called a discontinuous geographical distribution. Onoclea, no longer a native of Europe, is often cultivated. The fossil fronds from Mull, both sterile and fertile, differ scarcely at all from those of the living fern. Records of the rocks show that Onoclea formerly grew in north-western Europe and in Greenland, regions where, through the vicissitudes of climate, it long ago failed to survive. Evidence furnished by fossils and the facts of geological history affords a clue to the present discontinuous range: in all probability Onoclea originated on the Thulean continent, perhaps north of the Arctic Circle, whence it spread radially into America, Europe, and the Far East; in the European region it became extinct, sharing the fate of many other plants that were unable to survive the rigours of the Ice Age. Its territory was originally continuous; now it is restricted to North America and eastern Asia. Another member of the class to which the ferns belong is the familiar Equisetum, the horsetails: one species, closely comparable with the living ***Equisetum limosum***—widely distributed in north temperate and arctic lands—has been found in the sediments of Ardtun Head. Equisetum may be described as an emblem of changelessness: nearly related forms grew in Palæozoic forests at least 150 or 200 million years ago: less closely related plants in the same forests—the calamites—were comparable in size with trees. The slender horsetails of the Coal Age and their much more robust and woody allies remind us that in the course of evolution some of Nature's early experiments survived unaffected by the production of new competitors, while others, less successful, left no direct descendants. As we follow the march of plant-life through the ages, evidence of progress accompanied by retrogression becomes recurrently apparent: in the varying green mantle of the earth there can be traced threads running through the whole, changing very slightly as we follow them onwards and upwards, preserving all the time a remarkable uniformity in essential characters.

By far the greater number of the fossils from Ardtun are leaves of trees or shrubs which belong to one or other of the two great classes of seed-bearing plants. In Gymnosperms, including conifers and some other less familiar plants, the seeds are naked. In members of the other class, the highest, the most various and most abundant in the vegetable kingdom, the seeds are more efficiently protected and are contained in a closed case; hence the name Angiosperms. Conifers played a prominent part in the Hebridean forests, but their representatives were not such as we find in modern Europe. A single and well-preserved seed attached to a relatively large wing affords evidence of the occurrence of a conifer allied to the silver fir (*Abies pectinata*) and some other species commonly cultivated in Britain. Firs, using the term for trees belonging to the genus Abies, and excluding the spruce fir (Picea), now occur in Europe, northern Africa, northern Asia and America: there is no British species of Abies. The Mull seed, it is important to note, agrees most closely with seeds of firs now living in China and Japan. Among other conifers discovered in the plant-beds of Mull and Skye are Cephalotaxus, Cryptomeria, and Sequoia. Recent species of Cephalotaxus are comparatively small trees confined to the Far East; some kinds are cultivated in our gardens. The foliage of the Mull species bears a striking resemblance to that of *Cephalotaxus fortunei*, a small tree widely distributed in China. Another genus which we believe to have been a member of the Hebridean flora is Cryptomeria: the fossils from northern Ireland and the Isle of Skye include foliage shoots, cones, and pollen-grains. The solitary living species is the Japanese *Cryptomeria japonica*, which occurs also in China: this is the tree of the famous avenue of Nikko in Japan, a noble memorial of a peasant who was too poor in worldly goods to contribute the usual building stone or a bronze lamp to the mortuary temple of an emperor, and instead offered to plant trees to protect visitors against the heat of the sun.

One of the most interesting of all living conifers is the genus Sequoia, of which there are two species confined within the narrow strip of hill ranges bordering Oregon and California on the Pacific coast—the redwoods (*Sequoia sempervirens*) of the Coast Range, watered in the dry season by mists from the western ocean, and the mammoth trees (*Sequoia gigantea*, often called Wellingtonia) of the Sierra Nevada. (See map, *S.*) Sequoia is an impressive example of the light thrown by fossil plants on the past history and wanderings over broad regions of the earth's surface of trees that, without man's protection, would be in danger of extinction. In earlier periods Sequoia was almost cosmopolitan; it ranged over wide spaces in the Old and the New World and overstepped the limits of the northern hemisphere. Foliage shoots preserved in the sediments of Mull were in all probability borne by trees closely related to the living redwoods, trees which are well worthy of inclusion among the wonders of the world; they attain a height of more than 300 ft. and the rings on cross-sections of giant trunks that have been felled bear witness to an age of 3,000 years and more. They were growing where they stand to-day 1,000 years before the Christian era. Trees next of kin to the redwoods once lived within a short distance from the Polar Sea several hundred miles farther north than the present tree-limit. Another species of Sequoia, more nearly allied to the mammoth tree, lingered on in Britain long after the disappearance of the Thulean forests: this we know from the discovery of fossil twigs and cones in the sediments of an old lake on the edge of Dartmoor in Devonshire. The two surviving species live in splendid isolation, dreaming of a greater glory that was theirs, their memories stored with secrets man can never know.

There was another naked-seeded tree in the forests into which we have intruded, a species of Ginkgo, the maidenhair tree. The barbarous name 'Ginkgo', invented in 1712 by the German naturalist Kaempfer, is in the opinion of the Rev. Dr. Moule, formerly professor of Chinese at Cambridge, a false transcription of 'sankyo', which probably means hill-apricot. Leaves perfect in form and venation were found in the chalky sediment of a lake that filled a hollow in the Hebridean lava-field; they differ from the foliage of the living tree only in a few minor features detected by the practised eyes of Dr. Florin of Stockholm in the microscopical structure of the superficial cells. Dr. Simpson discovered Ginkgo pollen-grains at another locality. The story of the maidenhair tree has recently been told (*Science Progress*, January 1938), and the temptation to linger over it here must be resisted.

Ginkgo of all trees furnishes the most thrilling example of a link with the past; its history, compiled from fossils of many geological ages and in many parts of the world, is an enthralling romance. This is but one of many histories recorded in Nature's story-book which makes us share the thought of Edward Fitzgerald: "Yes, as I often think, it is not the poetical imagination but bare science that every day more and more unrolls a greater epic than the Iliad". It would be rash definitely to assert that the maidenhair tree still exists under strictly natural conditions as a wild tree of the forest. Botanists who have searched for it in China, the country believed to be its last home, failed to discover convincing evidence of the occurrence of specimens which could not be ascribed to man's agency. On the other hand, a few years ago a Chinese botanist expressed the opinion that Ginkgo still grows wild in the province of Chekiang in eastern China. The oldest living examples occur in China and Japan, often in places where, as is fitting, they are venerated as trees endowed with healing properties.

The history of Ginkgo has been traced to periods antedating by millions of years the Thulean forests: we do not know of what sort its progenitors were; but we know that it is a survival from an age too remote for us to measure in terms which we can fully appreciate. We also know that Ginkgo, now a lonely relic in the present world, is a primitive and isolated type, the sole representative of a large family, including many different members, all of which save the maidenhair tree long ago fell by the way in the struggle for existence. When the tree lived in the Hebridean forests it was common in other parts of the Thulean continent from northern Canada to Greenland and Spitsbergen, in North America, Europe, and Asia. It was as widely distributed geographically as oaks, pines, and firs in the modern world. The history of Ginkgo is a record of endurance, of persistence with apparently little change in an unstable world. When we recall the amazing life-story of the tree and its forbears the autumnal colour acquires a deeper significance: we see in the pale yellow of the leaves a reflection of the golden age of a family that left a precious legacy. Would that the maidenhair tree were endowed with the oracular power of the oaks of Dodona and, in the trembling accents of its fluttering leaves, could tell us not of the future but of the varying fortunes of the family as age succeeded age.

The Ginkgo of Mull was not the last of its race in Europe: well-preserved remains have been found in younger rocks in France and Germany, proving that it survived in the Western world, though probably only in a few places, to an age preceding by a comparatively short period the invasion of temperate Europe and North America by arctic ice-sheets and glaciers, which had a far-reaching effect upon the vegetation in the Western world.

Leaving the naked-seeded plants, we pass to the flowering plants or Angiosperms. This class is more recent in origin than the Gymnosperms, at least so it would seem, and as in present-day floras so also in the Thulean forests, flowering plants contributed the greatest number of genera and species. We shall take first a few trees and shrubs which have descendants still living in Europe, and afterwards mention others that have no near relations in European floras. There were, we think, three or four kinds of oak, all different from those now living in Europe and America. The largest leaves from Mull assigned to the genus Quercus are oval, with a broadly rounded base and relatively small teeth; they resemble the foliage of a few Indian species, but the oak with leaves most closely resembling the fossil form is *Quercus serrata*, a native of China, the rain-forests of Assam, Japan, Korea, and the Himalayas. A second species from Mull is closely comparable with other Indian and Far Eastern oaks; and a third form of leaf is very similar in shape and venation to a species that now has its home in China, Assam, and the island of Formosa. It is noteworthy that none of the oaks of the Thulean forests conformed in pattern of the foliage to our familiar British trees.

One of the most conspicuous trees in the Hebridean woodland was a plane (Platanus) with large handsome leaves almost, but not quite, identical with those of the existing occidental plane of North America. The fossil evidence in this instance is supplied by male flowers and fruit-balls as well as leaves. As in all living planes, the expanded base of the leaf-stalk enclosed and protected a bud. There is, however, one interesting feature in which the leaves of the Mull tree differ from those of any living plane: there were two fairly large leaflets attached to the long leaf-stalk between the main part of the leaf and the base of the stalk. The significance of this peculiarity need not be discussed; it is one of those botanical problems of academic interest which excite the specialist. A more important fact for us is that plane trees in the period we are considering occupied a territory which extended very much farther north than the present area of distribution. Remains of plane trees have been found as far north as Spitsbergen in rocks approximately equivalent in age to those of Mull.

There are in the world to-day six or possibly eight different kinds of plane: the oriental plane (*Platanus orientalis*), the only species native in Europe, is one of the noblest living trees; it recalls the groves of the Academy in the golden age of Greece. One of the oldest specimens is the venerable stump bearing enormous arms in the market-place on the island of Cos where, legend would have us believe, Hippocrates, more than two thousand years ago, gave advice to his patients under the shade of the youthful tree. The oriental plane extends from Greece and the Aegean islands eastward to Asia Minor and the Caspian Sea; it is sometimes said to be wild in Persia and northern India, but more probably this eastward spread should be attributed to man. The most widely distributed species in the New World is *Platanus occidentalis*, growing usually in river valleys from Lake Ontario to Florida and west to Texas and Nebraska (see map, *p.* 417, *Pl*). On the western side of North America there are other species, in Mexico and along the Coast Range hills of California. The most familiar cultivated species in Britain is *Platanus acerifolia*, the so-called London plane: this favourite urban tree is regarded by some botanists as a hybrid between the oriental and the occidental plane; the time and place of its origin are not known with any certainty.

The geological record of Platanus affords a striking example of contrasts between past and present areas of distribution. Some of the oldest known fossil leaves and fruits are from early Cretaceous beds in Greenland, at least 300 miles north of the Arctic Circle. The occurrence of these remains, in sediments that were deposited in a remote northerly estuary before the chalk of the British Isles had been upraised from the sea-floor, affords definite proof that plane trees lived in arctic forests millions of years before they spread to the southern part of the Thulean continent. The birthplace of Platanus may have been in the far north, whence in course of time it spread to Iceland and Spitsbergen, from arctic to temperate North America and Europe, and wandered as far east as Sakhalin Island on the eastern confines of Asia.

One of the comparatively few trees in the Hebridean forests related to recent British species was a Corylus with leaves similar to those of our hazel but still more like the foliage of species now living in India and the Far East. Hazels were associated with planes not only in the ancient flora of Mull but also in circumpolar forests from which they travelled, in response to the urge of climatic change, to fresh and more genial homes farther south. Another tree in the Thulean forests was a cornel, a species of genus Cornus, which has a far flung distribution, in arctic and sub-arctic countries, in North America, Europe, and Asia. While fully conscious of the danger of placing excessive trust in leaves as evidence of affinity, we believe that a Chinese cornel (*Cornus chinensis*) agrees most closely in foliage with the Mull species. The cornels are members of an old stock represented in northern forests as long ago as the Cretaceous period.

Among the larger fossils from Ardtun Head are a few almost perfectly preserved leaves of a vine, which we believe to be specifically identical with specimens previously discovered in Alaskan rocks of approximately the same geological age as those associated with the lava-flows of Mull. Similar leaves have been described from Greenland, Iceland, Spitsbergen and more southern localities in America and Europe. Vines were widely distributed even as far back as the Cretaceous period: there is now only one European species, the wine-producing *Vitis vinifera*; but its leaves are unlike the fossils from Ardtun. The striking contrast between the present distribution of the vine in Europe and its former, much more extended distribution which included arctic and north temperate regions, raises the difficult problem of changes in climate from one age to another. Vine scrolls are a fairly common ornament on early Northumbrian Anglo-Saxon crosses, a motif adopted in still earlier ages by Greek and Roman sculptors, which, after the lapse of centuries, reached the highest expression of naturalistic treatment in England in the last two decades of the thirteenth century. Millions of years before vine leaves and fruit were fashioned in stone, one kind lived in pre-human days on the Thulean continent; and it is noteworthy that its nearest counterpart in the modern world occurs in the Far East.

We turn now to trees and shrubs belonging to genera which are no longer living in Europe. The first tree to be considered furnishes a striking contrast, in the narrow limits of its present geographical area, to the widely spread cornels and oaks. Cercidiphyllum is now confined to Japan and mountain valleys in some parts of China (see map, *C,C.*). The name Cercidiphyllum was chosen because of a superficial resemblance of the leaves to those of the Judas tree, *Cercis siliquastrum*; only a single species, with a few varieties, has survived, *Cercidiphyllum japonicum*, familiar to many tree lovers who cultivate it for the sake of the exceptionally beautiful gold, pink, and red parti-coloured autumnal foliage. In common with some other trees of ancient lineage, Cercidiphyllum lacks any near relations in the present age; it is one of a select company of Nature's anachronisms. Like the Maidenhair tree, it is an aberrant type, a relic living within a comparatively small area in the Far East: formerly it was one of the most widely distributed forest trees on both sides of the Atlantic Ocean. Several beautifully preserved leaves have been found in the plant-beds of Ardtun Head, leaves and occasionally fruits of Cercidiphyllum have been found in Grinnell Land and Ellesmere Land on the north-eastern corner of the Canadian Archipelago, in Alaska and at several localities on the Pacific and Atlantic coasts of North America, in Greenland, Iceland, and Spitsbergen, as well as in Switzerland and other parts of Europe (see map). Leaves, superficially at least indistinguishable from those of the existing species, are recorded from sedimentary beds in the valley of the Potamac River in Maryland assigned to the early days of the Cretaceous period when flowering plants were comparatively few in number and had not yet come into their own as the dominant class in the plant kingdom. When we remember the remote antiquity of Cercidiphyllum and its wanderings over the earth's surface during the passing of millennia, the autumnal glory of its foliage is enhanced a hundredfold and acquires a symbolic meaning.

The plant-beds on the headland of Ardtun have yielded very few recognizable fruits and seeds. Among the rare examples of fruits are some, about half an inch long, consisting of a slightly elongated seed-vessel surmounted usually by five leaflets, the enlarged and persistent covering of the young flowers, which served as efficient aids to dispersal by wind. The fossil winged fruits and associated leaves present a remarkably close resemblance to those of some living species of Abelia, a genus named after Mr. Clarke Abel, who discovered the shrub in China about one hundred and twenty years ago. Abelia is a member of the honeysuckle family (Caprifoliaceæ): most of the existing species have their home in Central China and are cultivated as flowering shrubs in European gardens. There are a few species in Japan, the Himalayas, and Mexico. Fruits of a Chinese Abelia agree most closely with the fossil specimens. Similar though not specifically identical fruits were discovered thirteen years ago by Mrs. Clement Reid and Miss Chandler in a collection of fossil plants from Bembridge in the Isle of Wight. The Bembridge flora is younger geologically than the flora of Mull and indicates a warmer climate. Other examples were recorded long ago from south-eastern France. It is therefore clear that shrubs next of kin to Abelias now living in China were once native in western and northern Europe. The introduction to British and Continental gardens in our time of Abelia, Cercidiphyllum, and other trees and flowering shrubs may be described as the reinstatement, through man's desire for horticultural novelties, of plants that had long been exiles from Western woodlands, where as natives they were never seen by human eyes.

So far, attention has been confined to a selection of plants identified from leaves and a few fruits. If time permitted, the list could be substantially enlarged by inclusion of the interesting results of Dr. Simpson's intensive study of pollen-grains, which he found by microscopical examination of broken-up pieces of lignite and coal, associated with sandy beds in Mull and on the adjacent peninsula of Morven. The pollen-bearing layers of rock are below the basaltic lavas and therefore slightly older than the leaf-beds of Ardtun Head. Dr. Simpson discovered several conifers and flowering plants confirmatory of identifications based on leaves; he also made many additions to the list compiled from leaves, fruits, and seeds. Three of his discoveries are selected for brief reference. He found pollen-grains of two kinds of alder (Alnus): the pollen of alders has a very characteristic structure and can easily be recognized. The occurrence of alders in the Hebridean flora supplies one of the few links between the extinct and the present European vegetation. The second genus chosen from Dr. Simpson's list is Magnolia: it is now represented by many species, both trees and shrubs, and is widely distributed on two sides of the Pacific Ocean: in Asia along the Himalayas and in parts of Tibet, over a large area in China, Japan and Korea, the Malay Archipelago, and Indo-China; in America from southern Ontario as far south as Central America and Cuba. It was shown many years ago that Mangolia formerly lived in Europe and flourished as far north as lat. 70° N. in Greenland; we now know that it played a part in the adornment of the Thulean forests.

Finally, a few words on the discovery of pollen-grains believed to belong to a species of Nelumbium: this genus is one of the most attractive water plants, a plant held sacred in ancient Egypt and venerated in the Far East. One of the living species is the sacred lotus, native in China and Japan and established as far west as the Caspian Sea; the other species has an extended range in North America, spreading as far south as the West Indies and Brazil. Nelumbium no longer grows in the Nile: long years ago it had a wide distribution in Europe, both in the Cretaceous period and in later ages. Looking backwards, we see its great circular leaves spread over the still waters of a Thulean lake.

It is important to note that Dr. Simpson's comparative investigation of fossil and recent pollen shows a preponderance of eastern Asiatic species in the Hebridean flora.

FANCY WITH FACT

We have attempted to re-create a scene in the past, and it is natural to ask—how does our reconstruction compare with reality? As it is impossible to satisfy curiosity by an actual flight to the Thulean continent, we can at least imagine ourselves miraculously transported to a destination where the past has become the present. At a very early stage of the backward journey we should see the greater part of the land being gradually obliterated by a covering of snow and ice; glacial conditions would be succeeded by a climate becoming more and more genial. Human beings would be missed before one-fiftieth of the flight had been completed. At last, after observing the moving panorama of land and sea, fluctuations in climate and changes in the character of the vegetation, let us imagine ourselves at the journey's end. Combining fact with fancy, we find ourselves, where in day-dreams we have often been, among the plants on the lava plateau. Thanks to the artistic co-operation of Mrs. Gwendy Caröe, it has been possible to give substance to our mental picture based on geological and botanical facts. It requires a special effort for us, who think of ourselves as overlords in Nature's realm, to visualize a world in which man has no place. Alone in a world which for millions of years to-come would be uninhabited by the human race, we could scarcely fail to look upon the beauty of Nature's pageantry with a strange and more penetrating vision:

> "Beauty, the eternal Spouse of the Wisdom of God
> and Angel of his Presence thru' all creation."

We should realize as never before man's insignificance: on the other hand, our estimate o spiritual values would be raised to a higher leve and we should experience a deeper sense of unio with the infinite. Our tendency is to think of the past, as we think of the present—in relation to man; we forget his very recent participation as an actor in life's drama. As we look at Nature as into a mirror, our own image obtrudes itself into the foreground. Had man been a dweller on the Thulean continent he would have seen, as we see, the sun by day setting in motion the living machinery of trees and herbs; the splendour of the evening sky; he would hear the wind in the trees, the music of running water and the songs of birds. The beauty of Nature is eternal. To the east and north beyond the lava-fields the Caledonian mountain ranges would be seen rising to greater heights than any of their peaks reach to-day; they were still to be exposed for millions of years to the destructive operation of Nature's sculpturing tools. Making a fresh demand upon our imagination, let us take a longer view over the curve of the earth towards the heart of Europe and far to the east to northern India. We should look in vain for the Pyrenees, the Alps, the Carpathians, and the Himalayas: these and other mountain ranges had not yet been lifted up; the time of their birth was not far off. We should see in their place a broad belt of water stretching from the Atlantic to the Indian Ocean, linking West with East. On the bed of this ancient sea—the Tethys Sea of geologists—sediments had long been accumulating, and these, with other rocks of igneous origin, would be involved at no distant date in a complete transformation of the earth's features and the crumpling of the crust into the "everlasting hills".

Returning to the Thulean continent at a place near the present geographical position of the Inner Hebrides, let us take a survey of the vegetation. We should be impressed by its luxuriance: at first sight the general aspect would seem familiar, but on closer examination of the trees and shrubs we should find only a few recalling modern European species; many would remind us of exotic plants of Eastern origin. Despite the immensity of the time interval separating us from the world we had left, we should not be aware of any such marked contrast in the general character of the vegetation as we might have expected. The plants had already put on their familiar dress and would seem to us surprisingly modern. But—and this would be the deepest impression—we should feel that we were among trees and shrubs that were reminiscent of remote Eastern forests. We should be conscious of the dynamic character of the plant-world; we should be driven to the conclusion that the forests were mainly composed of wanderers resting for a time in a temporary home whence, as conditions changed, they would pass to other stages in the long journey to their present refuges in Asia.

EVOLUTION

There remains another question which is always asked by those who attempt to reconstruct the vegetation of past ages: What contributions do the records of plant-life make towards a better understanding of evolution? The riddle of evolution remains a challenge and, as knowledge increases, we make fresh guesses. As a Cambridge friend writes in a recent volume of "Provocative Verse":

> "That life evolves was guessed of yore,
> Darwinians prove it true;
> Of how and why we know but little more
> Than old Lucretius knew."

The little more we know urges us to continue in hopeful expectancy the long and endless prying into Nature's methods. What then do we learn from the ancient flora of the Western Isles?

The facts do not substantially help us to trace the unfolding of life in the long interval separating the older part of the Tertiary era from the present time. There is little difference between the past and the present vegetation of the world as a whole in the nature of trees, shrubs and ferns: our knowledge of the earlier history of herbaceous plants is very meagre. The fossil flora of Mull represents an early phase of what may be called the modern type of vegetation, which overspread the world in the later stages of the Cretaceous period and has persisted with few major modifications until now. Evolution seems to have been characterized by bursts of production when new and successful types exercised a transforming influence; and these periods of exceptional creative activity were separated by periods of relative stability. The early Tertiary floras belong to a stage when a new order had become well established and an older order had passed its prime. The one great difference that emerges from comparison of the Mull flora and the existing European floras is not a difference in the components of the world forests, but a contrast in the geographical positions occupied by the various genera in the northern hemisphere: for the most part a Western home has been exchanged for a home in the Far East.

Drifting Continents

If we followed the vegetation on the southern part of the Thulean land farther to the north, we should be impressed by its apparent indifference to changing physical conditions as we travelled beyond the Arctic Circle; we should fail to notice any zonal distinguishing characters in the floras such as in our day reflect the passage from temperate to arctic regions. The evidence of fossil plants forces us to the conclusion that the vegetation on the Thulean continent, its northern boundary within a short distance of the polar sea, its southern border on the latitude of northern Ireland and western Scotland, was astonishingly uniform. How, we ask, can we explain this surprising and well-attested fact? There must, it is generally agreed, always have been climatic belts; high arctic and much lower temperate regions cannot have supported closely comparable floras possessing several species in common. Some of us are convinced that changes in geography from one period to another, land connexions where there are now arms of the sea, interference with paths of ocean currents and consequential changes in temperature are inadequate as explanatory causes. What then remains? Were it possible for us to make a survey of the Thulean continent as it was, we might find that the geographical relation of the northern part of the forest-clad land to the North Pole was by no means the same as it is now.

It is difficult, it is probably impossible, to explain the facts without calling to our aid the hypothesis of drifting continents usually associated with the late Prof. Wegener and recently discussed in an able book by Prof. A. L. du Toit of South Africa. This is a controversial subject beyond the scope of my address: I can do little more than reaffirm adherence to the view that plant records from rocks of many ages raise problems which seem to be insoluble unless we postulate movement and sliding of the earth's crust. As icebergs are slowly drifted by ocean currents, as masses of cumulus clouds rapidly changing shape pass across a blue sky; so, the rate of travel enormously reduced, large slabs of the outermost rocky shell of the world may have shifted their position in the course of geological time. It must, however, be admitted that as yet refined methods of measurement have not furnished any evidence of crustal movement. Dr. Nörlund of Copenhagen has stated that longitudinal determinations, carried out by the Danish Geodetic Institute in 1927 and 1936 with a modern transit instrument, both times on the same pillar at a locality on the west coast of Greenland, gave practically the same result. In his presidential address at the Norwich meeting of the Association in 1935, Prof W. W. Watts made an interesting and judicial reference to the Wegener hypothesis: he spoke of it as having been hailed by many classes of investigators as almost a panacea, and quoted one of several critics who called it a beautiful dream, the dream of a great poet.

Proof or disproof of the Wegener hypothesis will be forthcoming in the more distant future, when the precision of modern methods of measurement has been available long enough to provide trustworthy data. Meanwhile, we must be content to wait in sanguine expectation that an interpretation of the overwhelming evidence furnished by fossil plants will be provided by research workers in the geophysical field.

One of the most impressive examples of the bearing of fossil plants upon the fascinating problem of climatic conditions in the past has been furnished by Prof. T. M. Harris of Reading. The facts are briefly these: several years ago Prof. Nathorst of Stockholm described a large collection of fossil plants from rocks in Scania, the southernmost province of Sweden, demonstrating the existence of a flora many million years older than the one we have been considering. It was a very rich flora composed of numerous ferns, conifers, and other plants; it probably lacked flowering plants. More recently, Prof. Harris made a still larger collection of fossils during a long visit to eastern Greenland in the ice-bound district of Scoresby Sound where, under extreme arctic conditions, only a few stunted plants are able to exist.

Nothing could be more striking than the present contrast between the floras of eastern Greenland and southern Sweden. The arctic fossil plants of the same age as those from Scania demonstrate the former existence of a flora even richer than that from southern Sweden: comparison of the two floras affords no indication of any difference in the size of individual plants and no difference in the vegetation as a whole. A luxuriant and uniform vegetation occupied an area stretching from central Germany to southern Sweden and a thousand miles farther north beyond latitude 70° N. The fossils preserved in rocks at localities within this far-flung geographical area from south to north give no indication of any such change in the plant communities as we should expect and as we find when we contrast arctic and temperate floras in the present world. This uniformity, I venture to think, is inexplicable unless we assume a very considerable movement and reshuffling of the earth's crust. The geological historian needs the co-operation of astronomers and physicists in his endeavour to reconstruct the world at the successive stages of its development; he looks to them to prevent him from making assumptions inconsistent with conclusions reached by workers in other fields. On the other hand, geologists and palæontologists contribute facts that are incontrovertible however much they seem to be in opposition to the views of students whose primary interest is in geophysical problems.

NEGLECT OF EARTH HISTORY IN EDUCATION

There are still some people who ask, what is the use of the kind of information given in this address? My reply is that knowledge gained from a first-hand study of Nature, both animate and inanimate, has a value beyond price. Enjoyment of the romance of creation as recorded in the life of the past and of the present is within the reach of all who have the desire to read the open pages of Nature's book. In the rocks we find the soul of history: the whole world throbs with life, and the joy of it all is ours to share:

"I said it in the meadow path,
I said it on the mountain stairs—
The best things any mortal hath
Are those which every mortal shares."

We have caught here through the mists a glimpse of a scene on earth's stage separated from the present by a small fraction of time in relation to the whole span of geological history. The Thulean forests which we have visited included trees, shrubs, and other plants of surprisingly modern aspect, though it is not to be supposed that they were absolutely identical specifically with their living descendants; from the material available it is impossible to define or assess the difference. What we have seen throws little light on the evolution of the plant-world; it is equally true that the main conclusion forced upon us by our retrospect cannot fail to convince us that it is impossible to understand the present distribution of plants over the earth's surface unless we extend our survey into the past. Darwin spoke of geographical distribution as a noble science, "almost the keystone of the laws of creation". The living world cannot be fully appreciated as an expression of creative energy unless we free ourselves from the cramping influence of the environment in which we live.

As a botanist whose first love was geology, may I make a plea for wider recognition of physical geography and geology as branches of knowledge possessing an inestimable value as a means of bringing young people into close companionship with Nature and as a source of refreshment, a stimulus, and an inspiration. Most of us would probably agree with the spirit of a remark made a good many years ago by the late A. C. Benson: "I find it hard to resist the conviction that, from the educational point of view, stimulus is more important than exactness". Arguments in favour of introducing geology into schools were put forward in a report on scientific education presented at the Dundee meeting seventy-two years ago, and in 1936 and 1937 the Association published two reports on the same subject. Let me add another argument of no little value: Hugh Miller wrote in a letter to a friend: "Geology is, I find, a science in which the best authorities are sometimes content to unlearn a good deal". That is worth much: geology helps us to cultivate the not too common virtue of admitting that it is possible to make a mistake.

In conclusion, I cannot do better than quote with wholehearted agreement words spoken by Sir William Bragg in his presidential address to this Association eleven years ago: "Some speak of modern science as tending to destroy reverence and faith. I do not know how that can be said of the student who stands daily in the presence of what seems to him to be infinite". These words apply with equal force to searchers after truth whose main interest is in the living world, no less than to those whose objective is the elucidation of the structure of matter that is called by contrast dead and yet vibrates with life. The earth was once lifeless: when and how living protoplasm had its birth we do not know, nor do we know whereupon were the foundations of the earth laid. We can only echo in our hearts the voice out of the whirlwind:

"Whereupon were the foundations thereof fastened?
Or who laid the corner stone thereof;
When the morning stars sang together,
And all the sons of God shouted for joy?"

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

Instruments in Science and Industry

THE presidential address by Mr. R. S. Whipple to Section A (Mathematical and Physical Sciences) is largely devoted to showing how much the progress of the sciences depends upon the development of the instruments employed. A few well-known instruments are selected as examples—the microscope, telescope, spectroscope, etc. Their development has a long history and each can be adapted to yield accurate measurements by the addition of suitable devices.

One of the earliest scientific workers, the Dutch naturalist Leeuwenhoek, during the period 1674–1723, discovered by means of a single-lens microscope the protozoa and bacteria, and made many other discoveries of supreme importance. Although many variations in the design and mechanical construction of the microscope were made during the eighteenth century and the early years of the nineteenth, yet there is no invention of fundamental importance to record until the construction of the achromatic objective. This was first successfully completed by the French optician Chevalier about 1825. Abbe carried the corrections to a far higher degree of perfection, notably by using glasses of new types which at his suggestion had been worked out by Schott, to produce, about 1886, the so-called apochromatic objective. It is difficult to see how the resolving power of the microscope is to be increased further using light from the visible region of the spectrum; the alternative is the employment of rays of shorter wave-length.

J. E. Barnard has developed a successful technique in connexion with ultra-violet microscopy and has shown that it is possible to study and photograph living bacteria, which are normally transparent to light from the visible regions of the spectrum.

The use of short-wave radiation has proved so successful in the case of the ultra-violet microscope that great interest is being shown in the development of instruments using still shorter radiations. It is possible, in a suitably designed piece of apparatus, to use a beam of cathode rays to obtain photographs of bacteria and bacilli at magnifications as high as 20,000 diameters.

Although a Dutchman, Lippershey, discovered the telescope, yet it was Galileo who first produced an instrument worthy of the name. He ground and polished his own lenses and in 1610 discovered the satellites of Jupiter. Newton pointed out that the focal length of the refracting telescope could not be reduced owing to the refrangibility of light of different colours and the impossibility of focusing for all the colours simultaneously. In 1663, James Gregory suggested the reflecting telescope, and five years later Newton constructed the first satisfactory instrument.

Herschel made many specula of high quality, culminating in one of 4 ft. diameter for his Slough telescope. Owing to the increasing demand for telescopes of higher magnification, and of increased light-gathering power, the size of the mirrors used in modern instruments is steadily increasing. An instrument is now being constructed for the Mount Palomar Observatory in which the mirror is 200 inches in diameter.

The highest accuracy obtainable is required in the divided circles of astronomical and surveying instruments. In the latest form of theodolite the circles are made of glass, the divisions being etched upon them. The advantages of the divided glass circle are so marked that the new reversible transit instrument for the Royal Observatory, Greenwich, is provided with such circles, 28 inches in diameter.

The spectroscope is proving of great service in industry both as a tool for rapidly analysing samples of materials and for detecting impurities. The value of the instrument in advanced physical work cannot be easily exaggerated.

After discussing briefly the instruments used in the measurement of time, Mr. Whipple considers the importance of modern electrical instruments and the large part that will probably be played in their future development by the thermionic valve. In concluding, he stated that he was much impressed with the steadily growing demands for higher accuracy in all measurements. As new problems arise both in science and industry the requirements become more stringent. The instrument maker constantly receives incentives to progress from the scientific worker, to whom he owes not only suggestions but also many of his new materials. If knowledge is to progress, it is essential that theory and practice advance together. Nowhere is this more true than in the development of scientific instruments.

FILM REACTIONS AS A NEW APPROACH TO BIOLOGY

TOWARDS the end of the last century, the biologist considered that the biological entity was the whole living unit. In recent years the interest developed in specialized processes such as enzymatic reactions has tended to obscure approaches to the mechanism of co-ordination and integration of activities of a cell. Since an analysis of the colloidal properties of living matter reveals that a large fraction of the material and energy lies in a new phase, the interphase, it seems pertinent to inquire how far physical and chemical reactions may be modified when the reactants are confined to an interphase. This is the subject-matter of Prof. E. K. Rideal's presidential address to Section B (Chemistry). The general considerations in respect to composition and structure of the interfacial phases have long been known and have been exhaustively examined during the last twenty years. More recently, attention has been directed to the physical properties of monolayers of the macromolecules, such as the proteins and methylated celluloses and starches. These are of interest in that two-dimensional gels, prototypes of membranes, can be formed. The fact that the molecules in monolayers are orientated in respect both to the substrate and to their neighbours, and that this orientation can be affected by expansion or contraction of the monolayer, is shown to have an important bearing not only on the rates but also on the height of the potential barriers involved in the reactions. Many examples are noted in surface chemical reactions, including both enzyme activities and photochemical processes.

Since the molecules at the interfaces are orientated, in two component systems molecules of different species can be adlineated with respect to one another. Under these conditions the interaction energies comprising both the polar as well as the non-polar portions attain maximum values, and stable complexes frequently result. The formation of these complexes is brought about by the penetration of a monolayer of one species by the molecules of the penetrant. These penetrative reactions appear to be involved in various biological processes such as lysis, agglutination, or sensitization, and to play a part in the action of various drugs. Complexes formed in this way may be broken by other reactants and can likewise serve as carriers for an otherwise non-transportable reactant.

Penetrative reactions involve the penetration of a monolayer by a reactant containing but one reactive polar group. If the reactant contains two or more of such reactive groups, on injection beneath a monolayer the reactant will be adsorbed by the monolayer and form a series of interlinks. An extensive interlinking results in the formation of a non-dispersable tanned skin possessing distinct properties. Finally it is pointed out that action as opposed to injury currents can be imparted to such a system by periodic alteration of the orientation of the molecules of an interphase.

METAMORPHISM AND IGNEOUS ACTION

THE consideration of the relation between metamorphism and igneous action, which forms the subject of Prof. H. H. Read's presidential address to Section C (Geology), falls into two parts. First, a brief historical summary of the peculiarly national contributions serves to display the wide divergences in opinion on this question. The views of the Rosenbusch school of pure thermal metamorphism are contrasted with the imbibition notions of the French, and the work of Becke of Vienna, the Swiss, Sederholm of Finland and the Americans is reviewed. The classic investigations of George Barrow on zones of progressive regional metamorphism in the highlands north of Dundee and their causal relation to granitic injections are sympathetically summarized.

In the second part of the address, a discussion is presented of the origin of regional metamorphism, that is, of the transformations which have affected large portions of the earth's crust. Prof. Read objects to the customary view that regional metamorphism and dynamic metamorphism are equivalent terms, and suggests that, apart from the dominantly cataclastic effects produced in rocks by patent dislocations, metamorphism is not directly controlled by orogenic deformation. The preservation of original sedimentation textures, the coincidence of schistosity and bedding, the horizontality of schistosity over wide areas and mimetic crystallization generally are observed features which are incompatible with dynamic action.

To account for these features, the operation of a static or load metamorphism in which the transformation is considered to be due to the vertical pressure of superincumbent beds has been invoked by some. Objections to the validity of load metamorphism are, however, many. The existence of completely non-metamorphic rocks which have nevertheless been covered by an immense thickness of strata, high-grade metamorphic rocks resting on lower-grade rocks, and the narrowness of metamorphic zones are examples of these objections. Load, by itself, is not enough.

Prof. Read considers that metamorphism is not a function of depth. He suspects that the notion of the great depths of high-grade regional metamorphism flourishes because of the supposed necessity of carrying rocks down to be metamorphosed, and suggests that as an alternative we should consider bringing the metamorphosing agents up. This can take place in connexion with granitization and the formation of migmatites. Whatever be the origin of granitic magma, it has been demonstrated in dozens of localities that solid rocks have been converted into rocks of granitic character. In the production of such migmatites, replacement must be the essential process, and it is reasonable to believe that during this replacement there occurs an emigration of material into the country-rocks adjacent to the theatre of granitization. Around the migmatite core, therefore, zones of various characters depending upon the localization of different precipitation-fronts are formed.

One of the most firmly established facts of metamorphic geology is the close association of highest-grade metamorphic rocks, such as those of the sillimanite and cordierite zones, with migmatites. This association has been variously interpreted, but Prof. Read agrees with Barrow and others in seeing in it a direct causal connexion. These high-grade rocks, however, are but the final stages in the progressive series of zones which supply the common types of regionally metamorphosed rocks. It seems reasonable to suggest, therefore, that regional metamorphism as a whole is genetically related to igneous activity of some kind. Out from the central theatre of granitization there pass waves of metasomatizing solutions, changing in composition and in temperature as they become more distant from the core and promoting thereby the formation of zones of metamorphism about it. Relief is obtained in the outer and cooler zones by shearing, in the inner and hotter zones by internal reconstructions. Such a metasomatic metamorphism accounts for the superposition of high-grade on low-grade rocks, for the preservation of original textures, for the coincidence of schistosity and bedding, for the changes in chemical composition of the progressive zones and so forth.

Prof. Read's conclusion, which is offered for discussion, is that all rock transformations may be classed into two groups, those of dislocation-metamorphism associated with dislocations of the crust, and those of regional and thermal metamorphism, associated with igneous activity.

PERSPECTIVES IN EVOLUTION

THERE are some general problems regarding life and evolution which are best comprehended by analysis of long-range views of existence upon the earth. Some of these problems were restated in the light of recent knowledge by Prof. James Ritchie in his address to Section D (Zoology).

Investigation of the properties of living things has led to modification of the extreme mechanistic and vitalistic views of life and has gone far in reducing its mystery to terms of physics and chemistry. Theories of the cell as an electromagnetic unit and of life as the dynamic equilibrium between such units, or of life and the cell as originating in an etherial vortex are less convincing than the researches which show that certain activities of cells conform almost perfectly to the laws of osmotic systems, to Donnan's membrane equilibrium, and to catalytic action brought about by enzymes. None of these interpretations, however, reaches the ultimate secret of life, the quality of which is apparent in a perspective of evolutionary processes.

Living organisms have assorted and aggregated vast deposits of calcareous and siliceous ooze from the dilute solutions of the ocean, and have gathered great formations of coal and peat from the tenuous stores of carbon dioxide in the atmosphere. This is something quite different from the physical fate of gases or solutions, which normally progress towards maximum dispersal of their particles. Moreover, the evolution of life itself, from simple to more complex, is an increase in orderly arrangement apparently opposed to the thermodynamical law of increasing randomness. From this point of view the characteristic of livingness is that it appears temporarily to hold up or withstand the physical course of degradation of matter, if it does not actually reverse it, through its power of trading with the environment so that it can build up stores of high potential energy from materials of lower potential.

Another notable development which must influence evolutionary thought is the lengthening perspective of life upon the earth. Newer and consistent information about the ages of geological formations based upon the break-up of radioactive minerals in rocks emphasizes generally and in detail the stability of living organisms and the slowness with which evolution has taken place. It emphasizes still more the significance of man as an agent of change in the living world, for his active part in modifying life upon the earth is practically confined to our era and mainly to the last three hundred years. In that insignificant period he has wrought faunal changes in civilized lands which can be compared only with the great secular changes of world evolution.

Realization of the 1,200 million years through which life has been evolving leads to an attempt to view mankind and the future of man in evolutionary perspective. His past is insignificant in time; his long future is unknowable so far as science is concerned. But bearing in mind the impetus of evolution, it is reasonable to suppose that in the immediate future (geologically speaking) his progress will be continued towards perfection of social life and the widening of the social idea to include peoples and nations as well as individuals. What of his long future, in the vista of a thousand million years still to come? The history of life upon the earth makes it seem presumptuous to suppose that with the coming of man evolution should cease or should be tied for all time to come to trifling changes in brain-power or better social organization for mankind. It suggests that man, so far the greatest of the manifestations of life upon the earth, may be no more than a stage in life's progress and a milestone upon the path of evolution towards a greater future.

METHOD IN GEOGRAPHY

MR. A. STEVENS points out in his presidential address to Section E (Geography) that during the last thirty-five years, it has been customary in geographical writing to pay some sort of service to the concept of natural geographical regions as distinguished from the 'political' divisions of the earth formerly in use. Immaturity of thought is indicated by the terms in use: natural (physical) region, economic region, human-use region. It arises from the inclination to see the matter of geography as a duality and its method as synthesis or integration. Fertile scientific work, the definite emancipation from scholasticism of modern intellectual processes, has depended on confining each branch of study to a single material category, and this problem has not been solved in the case of geography. Neither synthesis nor integration is possible where the factors and conditioning circumstances are too complex and difficult fully to be enumerated, let alone evaluated, as they are in the field with which geography attempts to deal. As to method, the subject must limit itself to the analytic: further examination of the natural region concept should contribute to the definition of its matter.

The natural region must be defined with regard to neither the physical nor the human or economic severally, but to both in symbiosis, in natural synthesis. The natural geographical region is the organized or living region. Organization depends on occupation by man and the development of a system of communications the functions of which are analogous to those of both the circulatory and the nervous systems of living organisms. The functioning of such regions with special reference to space is the study proper to geography, as that proper to history is such functioning in time (or sequence). Space and time may not fundamentally be independent variables, but they may be made the basis of partial differentiation. There is the story of the evolution of communications from the porter to the aeroplane, from the smoke signal to the radio. There is also the question as to how precisely communications have managed space.

Organized regions have their ontogeneses. At a given time a region may be *saturated* and its development mature, as, some time in the past century and a half, occurred in Western Europe; or it may be undersaturated and juvenile as is the New World to-day. Until a certain degree of maturity has been attained, the region cannot be defined in detail. The conditions for saturation depend on the state of economic development.

The major natural geographical regions of Europe are the European countries. A geography of Europe not based on the characteristic European phenomenon of the nation-State is absurd. Spatially these regions are quite out of proportion to modern possibilities of communication, the means of organization and cohesion.

RATES AND TAXES

PROF. H. O. MEREDITH'S address to Section F (Economics) entitled "Rates and Taxes" is a plea for more serious consideration of the distribution of the tax burden through society in view of probable increase in the ratio of public to private expenditure.

It is alleged that while the policy of *laissez-faire*, as understood by the Victorians, has been abandoned, we have failed to develop a financial practice comparable in logical coherence with that of Gladstone. In consequence, our finance is more and more passive and less and less capable of advance in good time on constructive lines. "Instead of grasping our nettles, we wait until we are stung". Defect of intelligible principles is illustrated by the case of income tax abatements in respect of children, and the policy of derating; and the question is ultimately posed of whether any of our existing sources of revenue are really satisfactory with the exception of income tax and sur-tax and the duties levied on property passing at death. The case against indirect taxes upon commodities and the local rates is argued at considerable length, attention being directed particularly to the sinister influences which have in the past promoted indirect as opposed to direct taxation. The arguments in favour of these sources of revenue are also examined and the conclusion is reached that little, if any, force is attached to any of them here and now, whatever may be or have been the case in other countries or at other times. Special attention is directed to the disputable character of the widely held opinion that virtuous conduct may found a valid claim to exemption from taxation and vicious conduct establish a case for pecuniary penalty.

Finally it is claimed that these methods of raising revenue must inevitably, under modern conditions, distribute the burden of taxation partly in an indiscriminate and partly in a clearly noxious way. In its concluding section the address propounds the theses that taxation ought to be felt and that every citizen in a community ought to pay and know that he is paying at least some minimum contribution to the expenses of the State.

THE FUTURE OF FLYING

THE presidential address to Section G (Engineering) provides each year an opportunity for a survey of some aspect of engineering science which happens to be of especial importance at the time it is given. The subject chosen by Mr. Wimperis is "The Future of Flying". Of its importance at the present time there can be no doubt. Aviation is surveyed by the public with a tempered pride; pride it is true in man's achievement, but apprehension as to the use which is being made of it.

The aspiration towards winged flight was expressed with wisdom when, more than two thousand years ago, the Psalmist avowed his longing for "wings like a dove". Mankind possesses the power of flight—a marvellous scientific and technical triumph; but brilliant as was the work of the pioneers, the crown of achievement cannot be regarded as won until mankind sees that the wings gained are indeed the wings of a dove, not those of a bird of prey. Every new invention has its warlike use as well as its peaceful purpose, and each has challenged men's wits to ensure that good, rather than harm, shall result from the new discovery. To bend the newest invention of all, the conquest of the air, to the service of mankind is now his great task. In it, success is essential lest we presently find that it is the air that has conquered mankind rather than mankind the air.

That the cleaning up of the aerodynamic structure would carry aircraft performance much further than had hitherto been realized was first pointed out, little more than ten years ago, by Prof. B. M. Jones of Cambridge. This required that all excrescences should be removed, and of these some of the worst were then the interplane struts and wires. When that had been achieved it was realized that much of the equipment hitherto carried externally, especially in military types, must be put inside, and with that attained, after a severe struggle, there arrived the modern streamlined aeroplane with its undercarriage, and even its tail wheel retractable into the body of the structure.

As a consequence the speeds of military aircraft are now in excess of 400 m.p.h. and will rise to 500 and possibly even 600 m p h. But civil aircraft rarely go faster than 250 m.p.h., and it is doubtful whether it is economically advantageous to have even so high a speed as that. This at once makes a great difference between the two types. Moreover, the comfort and space needed for civil transport tend to produce a design of body which does not in the least resemble military requirements, and in so far as the civil types, in their really large sizes, come more and more to take the flying boat form, so are they the less like military types.

In Mr. Wimperis's view there will be no reason, once the international situation has cleared, why there should not be an agreed limitation, in respect of numbers or tonnage, of bombing aircraft—leaving the interceptor fighters entirely aside. It would be but cautious to agree on a limit to the speed of civil types; but as this would merely confirm what economic requirements would themselves require, it need be no hardship to anyone; excessively high speeds for civil types do not pay, are much more dangerous to passengers, are much more noisy to everyone, and need extravagant air ports.

SCOPE AND LIMITATIONS OF PHYSICAL ANTHROPOLOGY

ANTHROPOLOGY spreads its domain over unusually wide fields of scientific inquiry, and it is becoming increasingly impossible for the representatives of the different branches of the subject to maintain intelligent contact with each other and to judge of the validity of the evidence which is presented in branches other than their own. In his presidential address to Section H (Anthropology), Prof. W. E. Le Gros Clark discusses the present position of physical anthropology and its future prospects.

Intensive studies in comparative anatomy have established broadly the relation of man to the lower primates; but evidence of this nature is necessarily limited since it is often impossible to assess the relative taxonomic value of different anatomical or physiological characters The extension of our knowledge of the zoological status of man must now await the accumulation of palæontological data. The existing palæontological evidence of the origin of man is briefly reviewed, and stress is laid on the difficulties of interpretation when only fragmentary fossil remains are available for study. Physical anthropologists in the past have been somewhat too confident in the general inferences which they have drawn from such scanty evidence, and erroneous conclusions have frequently been based on an inadequate appreciation of the great range of variability in fossil and recent man. It is much more difficult than is generally supposed to draw even simple conclusions, such as those regarding sex and race, from the study of the skeleton alone.

The validity of taxonomic characters in the study of racial differentiation demands a careful study, and it is necessary that anthropologists should make more detailed inquiries into the genetic basis of the characters which they commonly use. There is evidence that even the shape of the skull is susceptible to nutritional and other environmental influences. Craniometrical evidence is further complicated by the possibility of parallel mutations, a phenomenon which is well known to occur with other physical traits. Consequently, craniometrical resemblances do not necessarily indicate correspondingly close genetic affinities. It is necessary to endorse the criticism of Prof. R. A. Fisher that, for the study of racial problems, physical anthropologists might more profitably direct their attention to living populations rather than rely on skeletal material, which too often is unsatisfactory and inadequate.

Apart from palæontology, it may be doubted whether physical anthropology as a historical science is likely to advance our knowledge of racial origins and racial differentiation very much beyond its present state with the techniques now commonly used. On the other hand, there are many profitable lines of inquiry which are waiting to be explored in other fields of physical anthropology. Many biological sciences have passed or are passing through what may be termed the 'museum stage' of their development, a stage involving the collection of material in the laboratory, its detailed examination and classification, and the interpretation of the facts which it presents in the form of general hypotheses. To complete its natural metamorphosis, physical anthropology should also now be emerging from the museum stage and developing along experimental lines or along the lines of active observation in the field.

The study of the bodily changes which man has undergone in the past gives a clue to the nature and extent of the changes which may be anticipated in the future. But what is far more important for the same purpose is the study of man as he is to-day. Sociological problems are becoming more and more forced on our attention which demand for their solution a conscious control of processes which have hitherto been left to chance. The improvement of health and physique and their relation to nutritional and climatic factors, the relative importance of hereditary factors in determining the distribution of physical characters, the results of the hybridization of different racial types, the effects on physical type of the redistribution of the populations of the world, the relation of changes in the reproductive rate to human variability and the composition of regional populations, all these are practical problems which can be approached systematically and scientifically only if we have adequate data regarding the physical nature of man in the conditions under which he now lives.

There is little doubt that the physical anthropologist of the future must be essentially a field-worker if he is going to develop his subject along progressive lines. Since, also, physical anthropology is one of the biological sciences, he must be a man of sound general biological training if he is to acquire a real insight into the problems which are set for him.

The science of physical anthropology has already contributed much to the study of the past history of the human species. By the study of modern populations it has a still more important function to fulfil, namely, the accumulation of data on the basis of which it will be possible in some measure to control the destiny of mankind.

THE ASSESSMENT OF PHYSICAL FITNESS

IN the House of Commons on Thursday, July 20, 1939, the Prime Minister said, "I am presenting a very serious argument. What is going to be the result of this increased expectation of life, coupled with the diminution in the birth-rate, which is going on at the same time ? In 1931 the number of persons of 65 years and over was, in proportion to the number of people between 15 and 65—the earning age—as 11 to 100. In 1955 that will have risen to 16 to 100 and in 1975 to 20 to 100. It may be said that that is a long way off and we shall not know anything about it, but surely we ought, if we have a proper sense of responsibility, to consider what is going to be the effect on the next generation of anything that we may be doing to-day. The implication of the figures have given is this : That as time goes on there will be an increasing proportion of the population who will be eligible for pensions and to whom pensions will have to be paid, and there will be a decreasing proportion of the population who will be earning wages and therefore able to make contributions to pay them."

In 1930, after the Contributory Pensions Act was passed, the cost to the Exchequer was £46,000,000. The estimates for the current year showed a charge of £69,000,000, and in the course of the next forty years the estimated annual cost will rise to £115,000,000 at the present rates of payment.

To blacken the picture still further, the only grade of the population that has a high birth-rate is the lowest in the social, economic and biological scale. It is therefore of importance to have some means of carrying out an audit of the physical fitness of the population so as to ensure a rational means of raising the general level of fitness.

Methods of assessing fitness are classified as somatometric, physiological and psychological. In his presidential address to Section I (Physiology), Prof. D. Burns reviewed the various indexes of fitness in general use and dealt with their validity. He restricted his discussion to the testing of subjects apparently healthy from the clinical point of view.

Somatometric assessment *per se* is of very little use as fitness is functional, depending not so much on the structure of the body as on the way it works, and on the speed and accuracy of the various correlations involved in action; and on the determination of the subject to do his best. Tests of cardio-vascular efficiency combined with some form of 'stunt' test may be considered reliable indexes of fitness.

MEASUREMENT IN PSYCHOLOGY

IN his presidential address to Section J (Psychology), Mr. R. J. Bartlett deals with measurement in psychology. In using the measurements of physics to evaluate the objective products of mental activity, psychology finds as an essential feature of its data a scatter which makes statistical treatment of that data necessary. No progress could have been made without accepting what Dr. Darwin, last year, in his presidential address to Section A, called "the fuzziness inherent in absolutely all facts of the world".

Intensity is a characteristic of sensory experience which has occasioned controversy that still leaves divided the committee of Sections A and J set up in 1932 "to consider and report upon the possibility of Quantitative Estimates of Sensory Events". Apparently much of the difficulty arises from confusion of two sources of 'error'. Sensitivity, in its true sense is a 'scatter error', would seem to be slightly superior to the demands of the Weber ratio, $\Delta I/I$, and is not subject to decrease with extreme stimuli. The rapid increase in the Weber ratio, as ordinarily determined, is due to a 'constant error', dependent on a memory factor and causing regression towards accustomed values.

After a review of experimental investigations of reaction times, bodily and mental work, and the physiological concomitants of emotional-conational experience, in which the methods and measurements used are those of physics and physiology, measurements peculiar to psychology are considered. In 1924 a Board of Education report on "Psychological Tests of Educable Capacity" concluded that intelligence tests were of value. The original 54 'manifold and heterogeneous' tests of Binet, compiled in 1905 for the diagnosis of mental deficiency, have become, in the 1937 revision of Terman and Merrill, two sets of 129 tests each, covering mental ages from 2 years to 22 years 10 months and measuring intelligence quotients up to 170 for children and 152 for adults.

Spearman's great contribution to work on intelligence was the introduction of methods of correlation to establish the value of tests. From his work he educed the two factor theory and tetrad criterion—a mathematical method of general application.

Work of the Industrial Health Research Board, the National Institute of Industrial Psychology and other research has given tests for abilities and skills of value in industry and for particular disabilities that unfit for certain occupations. These, as tests for vocational guidance and selection, are being used with increasing frequency.

There follows the measurement of personal attitudes and interests, as in the case of Thurstone and Chave's 'attitude to the Church scale', which enables a person's attitude to be assessed in a scale ranging from enthusiastic support to bitter antagonism. Similar methods have given social maturity scales and enabled a start to be made with the measurement of temperament and character characteristics.

Steady progress made, from measurement of sensory discrimination, through measurement of intelligence and measurement of abilities and skills, to measurement of attitudes and interests and measurement of temperament and character traits, justifies psychologists in expecting yet greater achievements and in not being unduly disturbed by the criticisms of those who continue to hold, with Malebranche, Leibniz and Kant, that psychological data contain nothing 'that can properly be called measurement'.

INTERPRETATION OF PLANT STRUCTURE

PROF. D. THODAY, in his presidential address to Section K (Botany), traces the change of outlook in plant anatomy from the adaptational and the phyletic to the causal and developmental.

Using xerophytes as example, he shows how difficult it is to assess the functional effects of structural features with exactitude. Xerophytes co-existing in the same habitat vary greatly in the efficiency of their structural provision for controlling the loss of water and are not as a class characterized by low rates of transpiration. Contrary to teleological expectation, stomatal frequency is higher in plants growing in exposed places; it is affected by the degree of expansion of leaves, under different conditions, after the stomata have been initiated. Correlations between vascular tissue in leaf and stem, too, require a causal rather than a functional interpretation and point to the influence of one part upon another during development. The discovery of hormones in plants, especially of auxins, which among other effects stimulate cambial activity, justify such an interpretation of structural correlations.

Phyletic studies have had only limited success in the tracing of phylogenies, but have revealed numerous instances of parallel evolution. These direct attention to the nature of major changes, which do not present the haphazard appearance of those which cytology has revealed. It is suggested that, from the lowest chemical plane upwards, the important factors were inherent probability of particular changes, and *selection of harmonious changes*, in dynamic systems. The study of development from a causal point of view may therefore throw light on the nature of the major changes in evolution. The material for comparative morphology consists, not of three-dimensional, but of four-dimensional patterns.

Prof. Thoday then approaches seedling structure from a causal point of view. He suggests that the shoot and root apices, as organizing centres, determine between them the vascular structure of the hypocotyl, the variations observed reflecting different degrees of dominance and extent of influence of one or the other, in different species and at different phases of development. The number of strands of procambium reflects the early influence of the cotyledons, sometimes also of the plumule. Exarch protoxylem, with flanking strands of phloem, reflect the influence of the root, and represent the smallest symmetrical arc-segment of the repetitive root-pattern. Subsequent centrifugal development of xylem shows the increasing influence of the shoot. Adventitious roots, especially polyarch roots of Monocotyledons, and the successful culture of excised root-tips, show that the root apex is self-determining as regards its structural pattern. In dicotyledons, however, no secondary growth is initiated apart from the shoot.

Williams's experiments with rhizophores of Selaginella show that hormones may throw light on morphological problems. While, however, hormones may be agents in the correlation of development, they do not account for the processes that are correlated. By reference to the development of the adhesive disk and haustorium of *Viscum album*, Prof. Thoday emphasizes that differentiation consists in the active response of living cells to various influences, which in this example are largely external, but in ordinary plant organs are mostly internal. Inheritance of structure is thus inheritance of behaviour patterns, the subtlety of which transcends our present conceptions of chemical or structural change in chromosomes.

EDUCATION FOR INDUSTRY

IN his presidential address to Section L (Education) Dr. A. P. M. Fleming directs attention to the vital part which the manufacturing industries play in the economic life of the nation, and points out that the well-being of these industries depends on the personnel engaged in them, so that the education and training of this personnel is a matter of great national concern.

The function of industry is to transform raw materials into useful commodities, and in both the social and economic sense it is the manufacturer's responsibility to the State to effect this conversion with the minimum of waste of time, effort and materials.

Industry is never static and particularly is influenced by the continual accession of new scientific knowledge. Hence there must be similar mobility as regards the outlook on industrial education.

The education of industrial personnel is considered in relation to two main groups of employees —manual and non-manual workers—and embraces entrants from all educational levels from the elementary school to the university.

In progressive manufacturing concerns it is becoming increasingly the practice—and this applies to all grades of personnel—to seek entrants who have received an appropriate education in fundamentals and to provide the required specialized training during the early years of employment. This practice applies equally to skilled artisans, foremen, supervisors, draughtsmen, designers, salesmen, research workers and those who eventually attain the highest executive positions.

The industrial education of the future must envisage the continual addition of new scientific knowledge, which is the basis of all industrial progress and particularly the development of entirely new industries.

The increasing mechanization of industrial processes and the tendency to reduce hours of labour should enable technical instruction to be given in the daytime and thus eliminate part-time evening technical study, leaving leisure for cultural pursuits and opportunities for increasing physical fitness.

At present the facilities for imparting practical instruction within industry are by no means fully utilized, and there is need in this respect for greater co-operation between industrial concerns. The practical training of industrial personnel is a national service to be conducted irrespective of any narrow commercial considerations.

The raising of the school-leaving age will have the effect of rendering practical training more intensive and will bring into prominence the question of the length of time really required for the effective practical training of every type of industrial personnel. Greater co-operation is needed between industry and education in the matter of providing adequate teaching staffs, notably in connexion with the technical institutions and universities. Post-advanced courses will, to an increasing extent, bridge the gap between the adoption by industry of newly developed scientific processes and the availability of knowledge of such processes in text-books used for the more conventional teaching courses. The extension of scholarships and fellowships to industrial students is desirable, especially those of such character as lead from general education to actual employment in a job after university education has been completed.

Though the importance of education and training of an industrial character is stressed, it is appreciated that all education must be liberal, and even to meet the urgent needs of industry no technical specialization should be permitted which excludes the possibility of time being devoted to broadening the mind in both the mental and the social sense.

SCIENCE AND AGRICULTURE

SIR THOMAS MIDDLETON, who takes as the subject of his address to Section M (Agriculture) "The Farmer's Position and the Scientific Worker's Programme", refers to the well-known motto of the Royal Agricultural Society of England, "Practice with Science", and contrasts the fortunes of the farmer and the scientific worker a century after the motto was adopted. The progress made by science would cause astonishment to those who chose the motto ; the condition of agriculture would disappoint their hopes. Agriculture's achievements were then judged by the capacity of the country to maintain its people, and the soils of Great Britain supported about seventeen millions. To-day, although no doubt the quality of our farm produce has improved. our soils support some fourteen millions only. Moreover, as is generally known, the difficulties of farmers are so great that even in a year when Parliament has been greatly pressed for time and the Exchequer for money, much time has been given to the discussion of agricultural matters and some money has been spared for assisting the farmer. Aid has been called for since, in the post-War years, rising costs, low wholesale prices and uncertain markets have depleted the farmer's resources to an extent that makes the requisite treatment of the soil impracticable.

References are made to the incomes of arable farmers in north-east Scotland and eastern England which show that, when a moderate interest is paid on capital, the farmer's earnings in recent years have approximated to the wages earned by cowmen and shepherds. In the United States in the early thirties the farmer's earnings did not equal those of his hired men, and similar conditions were faced by farmers in other countries, such as Canada, Holland and Denmark. Poverty among peasants and agricultural labourers has been widespread. A Committee of the International Labour Office has recently shown that in twenty-three countries studied by it an improvement in the condition of land workers was urgently called for.

The reasons for the meagre reward of those engaged in the production of man's primary need are discussed ; some are due to the producer's fellow-countrymen, others to the farmer himself. The nature of the farmer's calling is such that he finds it impossible to equate supply to demand. Thus, as a competitor in the food market, he occupies a weak place and is compelled to accept as remuneration for his work what is left over after others in the food industries have secured a margin which satisfies them.

In the second part of his address Sir Thomas Middleton alludes to the increase in the financial resources of scientific workers in agriculture and claims that this increase is justified because of the value of the work to the nation. The fact that markets may be over-supplied, though unfortunate for the farmer, benefits the public.

In the United States, where surplus commodities created great difficulties for the administration, there was no limitation of scientific work because of surfeited markets ; on the contrary, all available scientific assistance was enlisted in an endeavour to recover from the recent depression. A similar lead has been given by our own forefathers. When, in 1839, Britain had passed through difficulties as great as those recently encountered in the United States, the agricultural leaders of the day took "Practice with Science" for their motto. Since science is incomparably better qualified to help and farmers are far more ready to seek its aid than before, we have now, in facing an uncertain future, reason to do so with the courage, as with the motto, of our ancestors of 1839.

After a brief reference to investigations in progress at some of our agricultural institutions, the subject of food supply in war is discussed. The coming of the aeroplane calls for changes in English farming which would enable food production to be increased rapidly should war break out. Attention is directed to the ease with which production was increased in Scot'and in 1917 and 1918 as compared with the very great effort required in England, and it is argued that many English farmers, who now keep their land permanently under grass, should adopt the Scottish system of the temporary ley. The principal change desirable in English methods is thus the change for which Sir George Stapledon argued so strongly in his address to Section M at last year's meeting of the Association. It is a change which, superficially, would appear to be easy. In fact it presents many difficulties which call for careful study, and study from different points of view. Scientific workers in framing their programmes should ask themselves how best they may contribute to a solution of this problem and thereby enable agriculturists to increase food production rapidly should the need arise.

Although all our usual foods would demand attention, the chief effort in war would be to secure an increase of energy-supplying food. At the present time about 70 per cent of our energy supply is imported. Experience in 1914–18 suggests that, farmed as Britain now is, it would be difficult in war to provide more than 35 per cent of our requirements. This was the percentage which the United Kingdom raised at home in the years 1909–13. In 1918, favoured by the season, the figure was raised to 42 per cent, but since that year the area under grass in Great Britain has increased by nearly four million acres, and land under grass is unlikely to provide even one-fifth of the human food produced by cultivated land under cereals and potatoes.

The duration of wars cannot be predicted, nor can we forecast the effect on sea-borne supplies; we should not rely on storage and shipping to supply as much as 65 per cent of the food we should need in a prolonged war. The food production campaign of the future may be required to aim at a six months' supply. Britain now has about 17 million acres under permanent grass; if on four to five million acres of the most suitable land temporary were to replace permanent grass, so as to increase the area of arable land to about 16½ million acres (the area of fifty years ago) and the fertility of this arable land was maintained at a satisfactory level, the production of 50 per cent of our food in war should not prove to be beyond the combined efforts of our farmers and scientific workers.

LOCAL SCIENTIFIC SOCIETIES AND THE COMMUNITY

PROF. H. L. HAWKINS, in his presidential address to the Conference of Delegates of Corresponding Societies, emphasizes the opportunities for team-work that these societies afford. While the society should not become too parochial in its interests, nor lapse into a picnic-club, its local and social aspects are both essential to its success. Interest, not erudition, should be the criterion of membership.

Much useful work in natural history depends on observation, so that topics accessible to the majority of members will give most satisfaction. A society in a coastal town can study marine conditions that would be outside the scope of one located in a midland city.

Every local society should control the mania for collecting. Great advances in this respect can be recorded; rarities are rarely exterminated to-day in the name of science. But some people still need reminding that it is criminal to celebrate a meeting with a long-sought friend by dragging home his corpse.

Collecting specimens, living or inanimate, dissociates them from their environment. Specimens become curiosities of little value without particulars of the circumstances of their occurrence. For inanimate objects the collector can, if trained to observe, record all the features of their environment that are likely to be significant; but where living things are concerned, an individual cannot deal with all the factors that may have influenced their occurrence. The arrival of a migratory bird may be controlled by the appearance of a particular insect, and this may depend on the growth of some plant the development of which may have been affected by the weather of the previous season. Here is the opportunity for team-work.

Local scientific societies have a splendid opportunity for compiling statistics of transient phenomena. Every recurrent seasonal event invites, and should receive, accurate observation and a permanent record. Each society should encourage its members to keep statistics on all such topics. Large-scale maps for plotting localities, and a card-index for the records, and perhaps a retired business-man to keep order, would soon provide a mine of information packed with unsuspected wealth.

This suggestion may be thought to be concerned more with the relation of a scientific society to science than with its reaction on the community.

Such a view is not only narrow, but also out of date. Prophecy is based on knowledge of past history. The statistics suggested above are the raw material of prophecy. If such truly natural history of a few decades were available, many of the problems that confront every farmer, and so every consumer, would meet at least partial solution.

In these critical times, statistics of the natural resources of the country are being eagerly compiled. There could be no better compilers than local residents trained to observe facts and to tabulate them methodically. Many of the problems involve elaborate technical study; but their fundamental aspects are within the capacity of any reliable observer. All who love their country can find here valuable and congenial work for which the need is urgent.

The number of people in any district likely to join, and work with, a scientific society is small. But the study of natural or human history should develop a philosophical outlook that can supply a tonic for the world, and mitigate the attacks of the flesh and the devil. The mere existence of a body of people that declares its interest in matters bigger than political squabbles, preferring wider vistas than those of the daily headline, should ensure a nucleus of stability in the quicksands of suspicion and opportunism where civilization is floundering.

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO., LTD., ST. ALBANS

meeting in an east-Midland town, when the question of dental service for expectant and nursing mothers was raised, a member declared that the husbands required treatment rather than the wives. The belief in the power of the caul to confer protection and good luck is gradually dying out, but at one time cauls were carried by the shore fishermen all along the coast of eastern England to protect them from death by drowning. In addition to the criminal use of savin and pennyroyal for abortifacient purposes, the legitimate employment of herbal remedies, especially raspberry tea, is widely spread in the eastern counties and north-east London for relieving the many inconveniences and minor troubles of pregnancy.

Ultra-Violet Lighting

MR. R. H. FINCH of the Lighting Section of the British Thomson-Houston Co. Ltd., has written a paper published in the *Electrical Review* for August 25 on the use in generating stations in war-time of ultra-violet lighting. The whole station could be bathed in ultra-violet energy and light produced only where needed, as, for example, on the handles of switches, meter scales, push buttons, telephones, doors, keyholes, tables, stairs, fire-extinguishers, etc., by the application to them of a dab of fluorescent paint or dye. Small press buttons should be surrounded by circles. Fuse positions can be delineated by outlining them, or by spotting the carriers with paint on the floor. In front of every switchboard a line should be painted about 12 inches away. The shape of every obstruction near an open switchboard or in a control room should be delineated by floor lines or patches of paint. Fluorescent chalks are also available for writing emergency warnings. The waves given off by the black lamps used are of a definite wave-length and produce no sun-burning or other dangerous effects. They are used in connexion with invisible fluorescent laundry marking systems and have been in constant operation for several years without a single case of ill effects to operators. Ultra-violet lighting is recommended for the emergency lighting in generating stations and similar premises in the Home Office A.R.P. Department pamphlet entitled 'War Time Lighting Restrictions for Industrial and Commercial Premises'.

African Linguistics

THE International Institute of African Languages and Cultures publishes in the July number of *Africa* a survey of linguistic questions relating to Africa, which includes a number of tasks with which the Institute is concerned. The issue by the Institute of a "Short Guide to the Recording of African Languages" has produced results of no little importance in their bearing on the study and classification of African languages. Prof. D. Westerman has compiled a list of no less than thirty-one previously and little-known languages which have been recorded through its use. This material has been sent to the Institute. Some will be published; the remainder, with such additional linguistic material as may accrue from time to time, will be available at the Institute for consultation by students. A valuable indication of the linguistic work already done, and of the field still to be covered in this department of investigation in Negro Africa, will be afforded by a series of articles which is to appear in *Africa*. The first in the current issue is a survey by Dr. Johannes Lukas of linguistic research between the Nile and Lake Chad. In addition to pointing out the regions to which future research can most usefully be directed, the series will serve as a preliminary classification of African languages. An interesting problem is discussed by Prof. C. M. Doke, who deals with the position and relation of European and Bantu languages in South Africa. While he admits that owing to political and economic factors European languages, and especially English, are ousting Bantu, he maintains that certain of the Bantu languages will persist for their cultural value in literary development and their private, family, and devotional use. Other contributions to this issue of *Africa* deal with indigenous literature, the study of intonation and of phonetics, and the facilities for the study of African languages in Great Britain, on the Continent and in South Africa. Consideration of the relation between language study and anthropology is reserved for future consideration.

Why Smallpox?

IN an editorial so entitled in *Public Health Reports* of June 23, it is stated that the United States leads all the other nations in the world except India in the number of smallpox cases reported in 1937, when there were 11,673 cases in that country. In 1938 the disease was more prevalent than it has been during the past five years, the number of cases being approximately 15,000. In 1936, according to the Health Section of the League of Nations, England and Wales, with a population of 40,839,000, reported only 12 cases. France, with 41,906,000 inhabitants, reported 273 cases, and Germany with a population of 67,346,000 had no cases. Some of the States in the Union have had no smallpox for several years. New Jersey, for example, with a population of about 4,400,000, has not had a case for more than seven years, while the States of North Dakota, South Dakota, Montana, Idaho, Oregon, Wyoming and Utah, with a combined population less than that of New Jersey, reported a total of more than 12,000 cases during the same period. The persistence of smallpox in the United States is simply due to neglect of vaccination, the explanation though not excuse for this being the comparative mildness of the disease in recent years and the reduced incidence compared with fifteen or twenty years ago. The possibility of the malignant type developing from the mild type is a disputed question, but there is always the possibility of the malignant type being introduced from foreign countries, especially in these days of air travel.

Olfactory Electricity

IT is stated in the *Beama Journal* of July that electricity is now being used to measure a smell. Various electrical devices are used in everyday work to make measurements in the domain of sight, touch and hearing and in some cases high accuracy can be obtained. We feel sure that if demand for a practical application of this device is sufficiently great it will develop into new applications just as photometry, telephony and television have developed. The first application is to measure leakage from gas mains. In this case a snout or 'trunk' is constructed of such a shape that it can conveniently be poked into crevices along the gas mains. The operator presses a button and if there is a leak a sample of the gas is inhaled quickly into a test chamber, where it flows over an electrically heated platinum wire and registers on the meter the percentage of gas present. We are told that the electric device can do something which the human nose cannot always do. It can tell infallibly the difference between town's gas and sewer gas.

U.S. Industrial Research Laboratories

A SIXTH edition has recently been issued of the valuable list prepared by the National Research Council of the Industrial Research Laboratories of the United States (Washington, D.C.: National Research Council. Pp. 270. Paper cover, 2.50 dollars; cloth, 3 dollars). It consists of an alphabetical directory of commercial companies in the United States which maintain research laboratories, and is compiled from information obtained in each case from the director of research of the laboratory concerned. In asking for this information, it was pointed out that laboratories concerned merely with routine testing should not be included, but it was left to the director of research to decide whether his laboratory came within this category or whether it could be said to conduct research. The present list comprises no less than 1,769 entries, each of which gives such data as officers-in-charge, address, fields of science or engineering represented, research activities, publications, co-operative research supported and number of personnel. Federal, State and municipal laboratories are not included, except the National Bureau of Standards, while those in educational institutions have been omitted unless they are directly supported by industry. Four indexes are provided: serial publications; geographical distribution; principal personnel; and subjects of research.

Spectrochimica Acta

IN May, Messrs. Springer of Berlin published the first number of *Spectrochimica Acta*, which is to be devoted to research in the domain of chemical spectral analysis (see NATURE, 143, 468; 1939). The first number has 92 pages, 17 cm. × 25·5 cm., 82 of which are devoted to papers on changes of intensities in spectra of aluminium alloys (in German), quantitative analysis of solder, spelter, magnesium and aluminium alloys (in English), quantitative estimation of europium in samarium (in German), a new use of emission spectra in local spectro-analysis (in German), the use of the arc in spectro-analysis (in German). The remaining pages contain abstracts of papers published elsewhere prepared by more than forty specialists. The price of the number is 8.60 gold marks, which at the present rate of exchange is about 15*s*. and seems unduly high.

Land-Speed Record

THE water-speed record set up on August 19 by Sir Malcolm Campbell has quickly been followed by a new record for speed on land. Mr. John Cobb, of London, in his Railton Red Lion motor-car, at Bonneville Salt Flats, Utah, is reported to have reached an average speed of 368·85 m.p.h. over a measured mile. The previous record of 357·70 m.p.h. was set up over the same course last September by Captain G. E. T. Eyston.

Dundee and District

A NOTEWORTHY and welcome feature of the "Scientific Survey of Dundee and District", prepared for the Dundee meeting of the British Association (Dundee: B.A. Reception Room. 2*s*.) is the inclusion of a new and very fine geological map of the country around Dundee. When it is remembered that the last official geological maps of most of this area date from last century (Angus, 1884, and East Fife, 1889) and that the last semi-official map was that prepared for the 1912 meeting of the British Association in Dundee, the value of the new map will be at once realized. The map, although not an official publication, was prepared in the Scottish Office of H.M. Geological Survey, and inevitably shows many changes in mapping when compared with the 1912 edition. These changes are in the main due to the revision work of the Survey officers in the Fife coalfields and to the researches of independent workers, as Allan, Balsillie, Cumming, and Walker. Geologists generally will welcome this new map. It is a pity that it has been bound into the volume instead of inserted in a bound-in envelope. A certain lack of uniformity of treatment is obvious in the natural science sections of the survey. This is due no doubt to lack of space, though it is very unfortunate that no room was found for mention of the geologists from Lyell, Hugh Miller, and Geikie onwards, whose labours have elucidated the geological problems of this very interesting part of Britain.

Announcements

THE second International Congress of Eugenics will be held at Bucharest on September 25–30 under the presidency of Prof. C. I. Parhon.

A LEAFLET of instructions for the correct application of the Schafer method of artificial respiration has been issued by the Royal Life Saving Society, 8 Bayley Street, Bedford Square, W.C.1, where it can be obtained free of charge.

ERRATUM.—In Table 2 of the letter by Dr. L. Hahn and Prof. G. Hevesy entitled "Phosphatide Exchange between Plasma and Organs" published in NATURE of July 29, p. 204, the percentage of organ phosphatide synthesized by the intestinal mucosa and the stomach have been interchanged; they should read: intestinal mucosa, 10·0; stomach, 4·1.

Measurement of Neutron Dose in Biological Experiments

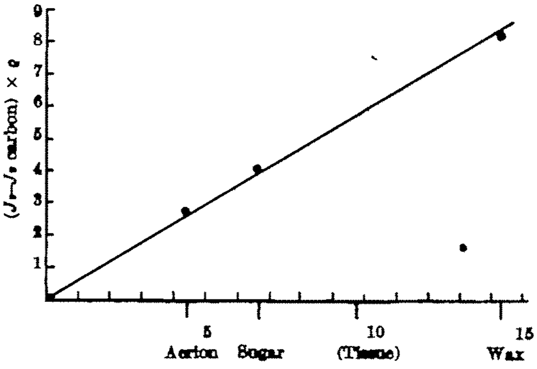
ZIMMER[1] has attempted an exact comparison of the absorbed neutron and gamma-ray energy required to produce an equal increase in the mutation rate in Drosophila sperm. In all other cases[2] neutron intensities have been measured in arbitrary units. In our own case[3] the unit dose was that amount of radiation which produced 1 E.S.U./c.c. of ionization in a graphite chamber having an air volume in the form of a disk 2 cm. diameter and 0·25 cm. deep. Taking as the unit of energy the increment of energy per unit volume of water subjected to 1 roentgen of gamma-radiation, we have now estimated the factor by means of which our arbitrary unit may be converted into energy absorbed per unit mass of tissue in three ways:

(1) The ionization produced by a beam of neutrons in free air has been calculated from the cross-sections for elastic recoil[4] and for nitrogen disintegration[5]. We estimate that 90 per cent of the recoil nuclei ionization and 40 per cent of the nitrogen disintegration ionization per c.c. of free air is measured by our graphite chamber. In addition there is the ionization due to the recoil carbon nuclei from the walls. This has been assessed in terms of the above mentioned data by comparing the ionization when the chamber was filled with pure oxygen with that when filled with air (0·71 : 1·0). A similar calculation gives the energy absorption in tissue ($H_2OC_{0\cdot2}$) and hence the conversion factor, which is found to be 7·3.*

(2) In the second method we avoided the use of collision cross-sections by comparing the ionization in the graphite chamber with that produced in chambers geometrically similar but with walls of 'Aerion'[1] ($C_6H_{4\cdot4}O_{1\cdot1}$), icing sugar ($CH_2O$), and paraffin wax ($CH_2$). Aerion and icing sugar are sufficiently conducting. The wax had a grid of graphite lines on it sufficient to produce a saturation field for gamma-ray ionization. As we were not confident that there would also be saturation for ionization by recoil nuclei the measurements were repeated with the wax covered with thinnest gold foil. The two sets were compatible and convinced us that the wax chamber results were reliable. Unit ionization in the graphite chamber corresponded to 3·35, 4·35, and 6·50 E.S.U./c.c. in the Aerion, sugar, and wax chambers respectively. It can easily be shown[6] that if J_v is the ionization per unit volume, W the average energy expended in the formation of a pair of ions in the gas, N the number of neutrons incident per square cm., n the number of gas atoms per c.c., σ_i the collision cross-section for atoms of type i, f_i the fraction of atoms of type i in the wall, $\overline{E}_i$ the average energy transferred from a neutron to a recoiling nucleus of type i, ρ_i the ratio of the mean atomic stopping power of the wall to that of the gas for recoil nuclei of type i, then:

$$J_v W = Nn\left[\Sigma_i \frac{f_i\ \sigma_i\ \overline{E}_i\ \varphi_i}{\rho_i} + \sigma_g\ \overline{E}_g\ \varphi_g\right],$$

where φ is a fraction, depending on the dimensions of the chamber and the effective range of the recoil nucleus, which approaches unity when the range is great, as is the case with recoil protons which are responsible for the majority of the ionization in chambers of wall material rich in hydrogen. φ may be calculated with sufficient accuracy in other cases. σ_g, $\overline{E}_g$ and φ_g refer to gas atoms.



DEPENDENCE OF NEUTRON IONIZATION ON THE HYDROGEN CONTENT OF THE WALL MATERIAL.

Since the hydrogen recoil term is very much greater than that for carbon recoils, J_v multiplied by the stopping power of the wall material for protons would be expected to increase very nearly linearly with the hydrogen content of the walls and this was in fact observed (see accompanying graph). Applying the above equation to the five sets of data—graphite-air $J_v = 1\cdot0$, graphite-oxygen 0·71, Aerion-air 3·35, sugar-air 4·35 and wax-air 6·50, we estimated the values of $N\sigma_i\overline{E}_i$ for hydrogen, oxygen, and carbon, and hence the energy absorption per c.c. of tissue, which is $N[n_H\sigma_H\overline{E}_H + n_o\sigma_o\overline{E}_o + n_c\sigma_c\overline{E}_c]$. The conversion factor is thus found to be 6·4.

(3) Finally, all calculated constants may be eliminated by filling the chambers with mixtures chosen from hydrogen, carbon monoxide, and acetylene, so as to have the same atomic composition as the walls; since φ and ρ are then exactly unity

---

* Our former estimate of the factor 11·5 ignored the contribution from the disintegration of nitrogen and assumed somewhat different values for interaction cross-sections.

and the equation becomes

$$J_g \overline{W} = N n_g \left[f_H \sigma_H \overline{E}_H + f_o \sigma_o \overline{E}_o + f_c \sigma_c \overline{E}_c \right],$$

where n_g is the number of gas atoms per c.c. $\overline{W}$, the mean value of W for the gas mixture, was determined experimentally, relative to air, by means of gamma-rays. Measurements with Aerion, sugar, and wax would completely determine the three terms $\sigma_H \overline{E}_H$, $\sigma_o \overline{E}_o$ and $\sigma_c \overline{E}_c$. Unfortunately the 'sugar gas' measurements were not satisfactory—possibly on account of chemical action between the carbon monoxide and hydrogen under the influence of ionization—and so collision cross-sections were invoked for the *ratio* of the two small terms $\sigma_o \overline{E}_o$ and $\sigma_c \overline{E}_c$. The factor, determined in this way, was 6·9.

The three methods show satisfactory consistency, and suggest that a neutron beam which produces 1 E.S.U./c.c. of ionization in our graphite chamber will give the same energy absorption per c.c. of tissue as 7 roentgens of gamma-rays (± 20 per cent).

While the procedure which we have outlined is of general applicability, the particular value of the conversion factor is peculiar to a graphite chamber of the given dimensions, and to neutrons of about 3 Mev. energy. Comparison with Zimmer's results is, however, possible, since, through the courtesy of the German Cancer Campaign, the Aerion chambers used here were those used by Zimmer for Li-D neutrons. Dividing our factor of 7 by our observed ratio of neutron ionizations in Aerion and graphite, we obtain 2·1 as the figure by which the ionization in the Aerion chamber must be multiplied to obtain energy absorbed in tissue. Zimmer estimated this factor to be 1·8. The difference may in part be due to experimental error and in part to the different energy of the neutrons. Interaction cross-sections have been reported to show a marked dependence on neutron energy[7,8]. At the present stage of neutron dosimetry, the agreement must be regarded as satisfactory.

We gratefully acknowledge the financial assistance of the British Empire Cancer Campaign.

Microcalorimetric Measurement of the Mean Energy of Disintegration of Radium E

THE mean energy of the β-rays from radium E can be evaluated either by integration of the continuous spectrum of the electrons emitted by the source or by a calorimetric measurement. The calorimetric method permits the determination of the energy of the electrons independently of the secondary processes which take place while they are going through matter, and furthermore with practically the same precision for both slow and fast particles. It is, on the other hand, necessary to know for a given source the number of atoms which disintegrate per second and also the number of electrons emitted by each disintegrating atom.

Two calorimetric determinations of the energy of disintegration of radium E have been made earlier; one is due to Ellis and Wooster[1], the other to Meitner and Orthmann[2]. Their results are only accurate to within 10 and even 15 per cent.

We decided to repeat these experiments owing to the fact that the Radium Institute in Paris could provide us with strong radium E sources and also because we could measure the absolute value of the polonium content with a very great precision. Furthermore, one of us had perfected considerably the technique of calorimetric measurements in radioactivity[3]. These improvements resulted from the adaptation of Swietosławski's adiabatic microcalorimeter[4]. The principle of this calorimeter is as follows: with the help of a thermocouple, one maintains the same temperature in the calorimeter and in its surrounding water insulation, with a difference never exceeding a few ten-thousandths of a degree; the heat given out during the experiment is measured in such conditions by the increase in temperature of the water tank.

In our experiments the calorimeter was a nickel cylinder weighing about 10 gm., inside which the radioactive sample was placed in such a way as to allow no β-rays to come through before being absorbed by more than 3–4 mm. of nickel. The calorimetric capacity was tested by the measurement of the heat given out by a strong source of polonium (2,000–4,000 E.S.U.) deposited on a nickel foil, as was done with the radium E. This polonium source was measured with a precision of 1 or 2 per cent with the absolute apparatus of Mme. P. Curie[5].

The quantity x of polonium existing in the radium E sources at the beginning of the experiments was measured in the same way after deflecting all the β-rays by a strong magnetic field. This quantity, about 50–300 E.S.U., being at the limit of the sensibility of the apparatus, the precision of measurement is very small. Furthermore, the absorption of the alpha-rays by the radioactive deposit is very often not negligible. An evaluation of this absorption was made at the end of the experiments (when radium E has practically disappeared) by comparing the quantity of polonium determined by the calorimeter with that found electrometrically. Finally, in each set of experiments, x was evaluated within an accuracy of 10 per cent, which does not affect much the precision of the final results owing to the fact that our radium E sources were more than 40 mc. strong. The calorimetric measurement of the polonium at the end of the experiments allows us to evaluate at the same time, within 1 or 2 per cent, the quantity of radium E present at the beginning.

We made two sets of measurements: the first with a source of 80 mc. of radium E electrolytically deposited on a nickel foil ($x = 55$ E.S.U.); the second with 45·5 mc. of radium E deposited by evaporation in argon ($x = 270$ E.S.U.). In the second set, the calorimeter was filled with nitrogen in order to eliminate any possible influence of chemical reactions due to the presence of oxygen.

In each set of experiments the measurements made in the first 36 hours give values which are systematically too high. The measurements made in air (mean value: 323·6 ± 3·5 ekv.) are also slightly higher than those made in nitrogen (mean value: 317·6 ± 2·5 ekv.) and less coherent. The mean energy of disintegration of radium E deduced from our measurement is 320,000 ± 5·000 ev. The most probable value is rather near the inferior limit given by our results.

The detailed description of our experiments will be given elsewhere.

Thickness of Built-up Films

THE thickness of films built up on solid surfaces has formerly been measured by several methods: optically[1,2,3,4], by X-ray measurements[5,6], by the use of an interferometer[6], and directly with a screw-micrometer[6]. All these, except one modification of the first, required the deposition of some hundreds of layers, and the modification[4] involved a comparison with barium stearate films. During our investigation of protein films on solid surfaces, we have used a method which avoids this comparison and enables thicknesses of as little as 20 A. to be measured rapidly and accurately.

For a thin film on a metal surface the difference of optical path between the ray reflected from the film surface and that from the film metal interface is $d = 2\mu . e \cos \theta$, where μ is the refractive index of the film, e the thickness, and θ the angle of refraction. For minimum intensity of reflection, d must equal an odd number of half wave-lengths, that is, $4\mu . e \cos \theta = (2n+1)\lambda$, where n is any integer. Instead of keeping the wave-length, λ, constant and increasing e until two intensity minima are observed[1,2], we have measured the change in λ necessary to preserve an intensity minimum as the thickness of the film is increased by the addition of further monolayers.

The wave-length of the light which gives an intensity minimum for a given film-thickness was determined by means of a Hilger-Nutting spectrophotometer. This instrument is well suited for such measurements, since the monochromator enables any visible wave-length to be used for the photometric measurement, and the light reflected from the plates is polarized before passing through the spectrophotometer. Measurements must be carried out with the ordinary ray owing to the birefringence of the film. The accuracy of the method was tested with films of barium stearate deposited on stainless steel plates by the method described by Blodgett[1]. Measurements were made on films of ten or twelve monolayers deposited on a base of approximately forty stearate layers. The thick base is essential in order to bring the wave-length for minimum intensity into the visible region. Column *A* below gives the wave-length in angstróms for the intensity minimum of the base, *B* the number of monolayers deposited on the base, and *C* the new wave-length for an intensity minimum. The light was incident at 75°.

A	*B*	*C*	*D*
5550	10	6650	24·2
4990	12	6310	24·2
5060	10	6160	23·8

Column *D* gives the thickness in angströms per layer, t, calculated from the equation, $t = \Delta\lambda/(4\mu \cos \theta . \Delta N)$, where $\Delta\lambda$ is the wave-length increment, μ the refractive index[5], taken as 1·491, θ the angle of refraction, and ΔN the number of additional layers deposited. The validity of the method is established by the agreement of the calculated mean thickness of 24·1 A. for barium stearate with the value 24·2–24·4 A. obtained by other methods.

Further details, with the results obtained for protein films, will be published elsewhere.

Kepler's Law of Refraction

IN his review of the second volume of the new edition of Kepler's works in NATURE of August 19, p. 306, Prof. H. C. Plummer states that Kepler's formula for the law of refraction is

$$\alpha - \beta = k\alpha \sec \beta,$$

where α is the angle of incidence and β the angle of refraction. This reduces to the law

$$\sin \alpha = n \sin \beta$$

for small angles if $(1 - k)^{-1} = n$. Prof. Plummer also states that as the formula is really empirical, being founded on the flimsiest physical argument, it seems strange that a form so inconvenient for the derivation of β from α should have been adopted.

The following table which I published fourteen years ago in the *Notes of the Edinburgh Mathematical Society* may be of interest in this connexion:

α	β Vitellio's observations	Excess of β calculated by Kepler's formula over Vitellio's observations	Excess of β calculated by modern formula over Vitellio's observations
10°	7° 45′	− 11′	− 16′
20°	15° 30′	− 29′	− 39′
30°	22° 30′	− 19′	− 28′
40°	29° 0′	+ 2′	− 10′
50°	35° 10′	+ 14′	+ 4′
60°	40° 30′	+ 22′	+ 1′
70°	45° 30′	+ 19′	− 41′
80°	50° 0′	+ 0′	− 2° 22′

The first two columns give Vitellio's observations on air-water. The third gives the excess of β over Vitellio's observations calculated by Kepler's formula for $n = 1·317$ and the fourth the excess of β over Vitellio's observations calculated by the modern formula for $n = 1·333$. It will be seen that Kepler's formula agrees much better with the observations than the modern one does, owing to the last experimental value being very far out.

The result, of course, bears out the statements made in the previous paragraph of the review, that Kepler was no experimental physicist and that the experimental data at his command were incredibly slight.

Mechanism of Nitrogen Excitation in the Night Sky

THE light emitted by the night sky is a remarkable afterglow associated with recombination of atomic oxygen in the upper atmosphere[1]. Two normal atoms of oxygen could not recombine with emission of light; the recombination occurs only in presence of a third body to satisfy the principles of conservation. If that third body is an oxygen atom ^3P, it can attain the level ^1S by the following process:

$$O(^3P) + O(^3P) + O(^3P) \rightarrow O_2(X, v = 5) + O(^1S).$$

The total energy absorbed by the vibrations of the molecule and by the excitation of the atom ($0·93 + 4·18 = 5·11$ volts) agrees closely with the energy supplied by the recombination. Thus can be explained the emission of lines λλ 5577–6300 by the night sky. But if the third body is a nitrogen molecule in the normal state, the available 5·09 volts is insufficient to excite it, and we have to consider the three-body collision:

$$O(^3P) + O(^1D) + N_2(X) \rightarrow O_2(X, v_1) + N_2(A, v_2).$$

In such a collision the energy made available is $D = 7·05$ volts; hence the possibility must be considered of emission of Vegard-Kaplan bands $N_2(A \rightarrow X)$. Only those bands the upper level of which does not exceed 7·05 volts will be emitted, and the corresponding quantum number v_2 is at most equal to 5.

Now the upper energy levels of the most intense Vegard-Kaplan bands are $v_2 = 2$ and $v_2 = 3$. To find the cause of this selection, we must consider the vibration of the oxygen molecule after collision. To bring the O_2 molecule to the v_1 level, E_1 volts are necessary; and we have at our disposal only the difference $D - E_1$ for the N_2 molecule. Consider the necessary energy $A + E_2$ to excite the nitrogen molecule to the A state with the vibration quantum number v_2. We can admit that the excitation does not occur unless the available energy $D - E_1$ and the required energy $A + E_2$ are very close, calling in a resonance effect. The following table gives, on this hypothesis, the probability of emission of the Vegard-Kaplan bands.

	Energy available		Energy required		Difference
I	$v_1 = 0$	$D - E_1 = 7·05$ volts	$v_2 = 5$	$A + E_2 = 6·99$ volts	+0·06
II	1	6·89	4	6·83	+0·06
III	2	6·67	3	6·66	+0·01
IV	3	6·48	2	6·49	−0·01
V	4	6·30	1	6·32	−0·02
VI	5	6·12	0	6·14	−0·02

The transitions III and IV should be the most probable, thus explaining the intensity of the Vegard-Kaplan bands $v_2 = 3$ and $v_2 = 2$ in the spectrum of the night sky.

The probability of a collision of the second kind has been studied for a long while. It is granted that the probability increases as the difference between the exchanged energies decreases. Kaplan[2] quotes, in confirmation of this, the experiments of Bonhoeffer and Mohler on the fluorescence sensitized by atomic hydrogen. Following Kaplan, the formation of a molecule H_2 on vibration level v_1 requires a triple collision with a metallic atom capable of absorbing very exactly the liberated energy $D - E_1$ ($D = 4·34$ volts). Whence the possibility of emission from certain atoms (Na, K, Cd), whilst others (Zn, Mg) do not emit light.

Unfortunately the value of the dissociation potential of hydrogen accepted to-day is no longer 4·34, but 4·46 volts, and the coincidences that Kaplan thought he observed have disappeared. Also Kaplan has not apparently considered the rotation of hydrogen molecules. The total energy absorbed by a molecule is $E = E_v + B_v J(J + 1)$, where J designates the rotation quantum number. It would be sufficient, for the excitation of metallic atom to occur, that the required energy should be very near one of the possible values of $D - E$. But we multiply thus the theoretical possibilities of excitation, and metallic atoms, such as Zn or Mg, which have given nothing in the experiments quoted above, ought to emit the resonance radiation. The resonance potential of Zn is equal to 4·01 volts; that of Mg is 2·70 volts. Now, in the formation of a molecule H_2 ($v = 2$, $J = 7$), the liberated energy is 4·05 volts; it is 2·75 volts in the formation of a molecule H_2 ($v = 3$, $J = 7$). But perhaps the differences $4·05–4·01 = 0·04$ and $2·75–2·70 = 0·05$ volts are already too large to show excitation.

However, we observe also in the night sky spectrum a selection of the bands of the first positive system of nitrogen. The band λλ 6500–6550 emitted in the transition B ($v = 7$) → A ($v = 4$) is much the most intense. Now the excitation of the normal nitrogen molecule on the level B ($v = 7$) requires 8·71 volts, an energy which we do not find in the night sky. We must therefore consider the two consecutive transitions X ($v = 0$) → A ($v = 2$) and A ($v = 2$) → B ($v = 7$). The second absorbs 2·22 volts, which is only a little less than the 2·23 volts supplied by the O (^1S) atom in returning to the ^1D level. We can thus explain the enhancement of the 6500–6550 band in the sky by collision of the nitrogen $A(v = 2)$ molecules and oxygen ^1S atoms. In these collisions, the absorbed energy is equal (at about 0·01 volt) to the available energy.

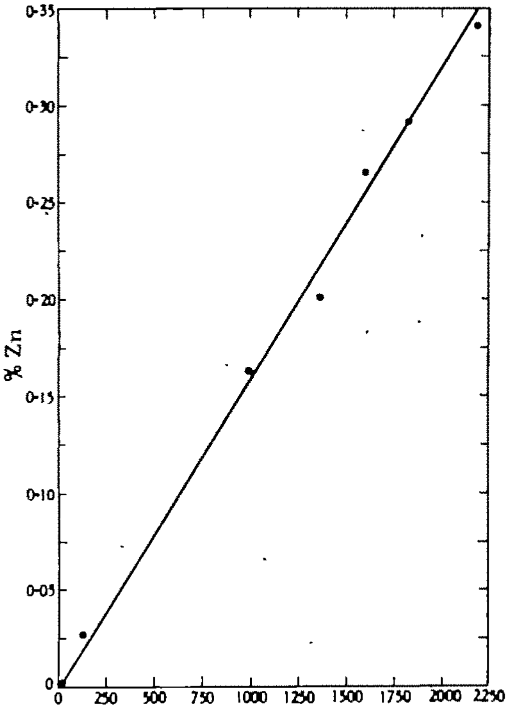
Carbonic Anhydrase

IT was shown by Henriques[1] that the rate at which carbon dioxide is evolved in the reaction $H_2CO_3 \rightleftharpoons CO_2 + H_2O$ is greatly accelerated by the presence of laked blood, mere traces of which are sufficient to catalyse this reaction[2]. That this acceleration is not due to hæmoglobin was clearly demonstrated by Meldrum and Roughton[3,4] who have separated from the red blood corpuscles a new enzyme capable of catalysing both phases of the above reaction. They described this enzyme under the name of carbonic anhydrase and gave a detailed account of its properties. Their purified preparation of this enzyme was a colourless substance, very active and sensitive to KCN, H_2S and NaN_3. The amount of this enzyme-preparation was, however, very small and scarcely sufficient even to recognize it with certainty as a protein compound. In the course of our study of metallo-protein compounds[5] present in the red blood corpuscles, we have found that the fractions of our preparations left after the complete removal of hæmocuprein had a very high content of zinc and a high carbonic anhydrase activity. By adapting our methods of purification to preparations on larger scale, such as 10 litres of blood at a time, and taking special care to increase the yield of the zinc fraction, we have obtained a highly active preparation of carbonic anhydrase. The activities of different fractions have been tested both by the manometric 'boat' method[3] and the colorimetric method[4]. The zinc in different fractions was determined by the dithizone and by the iodometric ferricyanide methods and was also isolated as a crystalline zinc quinaldinat salt.



RELATIONSHIP BETWEEN ACTIVITIES (AS DEFINED BY MELDRUM AND ROUGHTON[3]) AND ZINC CONTENTS OF DIFFERENT FRACTIONS OF CARBONIC ANHYDRASE.

From carefully washed corpuscles of 10 litres of ox blood, which give about 17 litres of alcohol chloroform extract, we have obtained about 250 mgm. of colourless protein containing 14·95 per cent nitrogen and 0·31–0·34 per cent zinc and showing a high carbonic anhydrase activity. This preparation tested chemically was found to be almost completely free of other metals known to occur in blood, such as iron, copper, manganese or magnesium. Moreover, the spectrum analysis of such preparations kindly carried out by Prof. H. Dingle confirmed the above results and revealed only traces of other metals. The fact that its zinc content has already reached such a high value shows that this preparation contains probably only one protein compound. The very high carbonic anhydrase activity of this preparation suggests, therefore, that the enzyme is the zinc-protein compound. This is, moreover, supported by three other considerations, namely: (1) the parallelism between the carbonic anhydrase activities and zinc contents in different fractions, at least up to our purest preparation (see accompanying illustration); (2) the perfectly reversible inhibition of the enzyme activity by KCN, H_2S and NaN_3 which are known as specific inhibitors of reactions catalysed by metallic compounds; (3) the absence of other metals in the highly active preparations of carbonic anhydrase.

By comparing the catalytic activity and the zinc content of our purest preparation with those of the laked red blood corpuscles, it appears that the total zinc present in the corpuscles belongs to the zinc-protein compound of carbonic anhydrase.

It may be mentioned finally that zinc belongs to the universally distributed micro-constituents of plants and animals and is therefore much more widely distributed in Nature than carbonic anhydrase. Like iron and copper, zinc forms probably with different proteins several compounds having different properties and functions.

Artificial Hibernation

As I have already shown in preliminary communications[1,2], artificial hibernation is produced in hedgehogs in autumn by giving them injections of magnesium simultaneously with insulin and transferring the animals to an ice-box. Thereby, for example, the heat regulation of the animals was disturbed, and they passed from a warm-blooded state into a cold-blooded one. At the same time, the blood sugar value was decreased to the level of that found in normal hibernation. In the first series of experiments I employed comparatively large amounts of magnesium and insulin. Similar amounts of insulin given without magnesium always caused fatal hypoglycæmia.

This summer I have continued the experiments with more material. The experiments have been carried out with fully awake hedgehogs at the end of June and at the beginning of July. Artificial hibernation was produced in these experiments in midsummer by administering to the hedgehogs subcutaneous injections of magnesium simultaneously with insulin and transferring the animals into an ice-box (at + 2 – 5° C.). The amounts injected were much smaller than those used in autumn (usually 0·5 c.c. 1 mol. magnesium chloride and 4 I.U. insulin per 480–750 gm. body weight). The same amount of magnesium only and cold had no effect on the animals; but on the other hand, the same amount of insulin only and cold caused the hedgehogs to go into artificial hibernation. Laufberger[3], Dworkin and Finney[4], and Dische, Fleischmann and Trevani[5] have also produced artificial hibernation with insulin injections. Especially noteworthy is the considerable increase of serum magnesium in the hibernation brought about by insulin, as in the natural hibernation[6,1].

	Blood sugar (mgm. %)	Serum Mg (mgm. %)	Ca (mgm. %)
Normal hedgehog	109	2·5	11·4
Artificial insulin hibernation	38	4·4	11·0
Natural deep hibernation	49	6·1	10·6

The hedgehogs have remained hitherto in the artificial hibernation continuously for 10 days.

When the animals in which hibernation was induced with both magnesium and insulin or with insulin alone were removed from the ice-box to a warm temperature (21 – 23° C.) they awoke in a natural manner and returned again to the warm-blooded state.

A more detailed account of the investigations will appear in the near future.

Mesomerism and Orientation

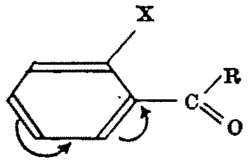
THE brief reference to the apparently anomalous nitration of the acetyl derivative of 2-*m*-xylidine to a 4-nitro derivative and its interpretation in the paper just published by Ingham and Hampson[1] makes it desirable to point out that many of the anomalies associated with ortho-substituents (and usually grouped under the heading of 'ortho effects') find their explanation in the steric hindrance of resonance discussed by Ingham and Hampson. This view had been arrived at independently in connexion with a systematic study of isomerizations produced by aluminium chloride[2]. It is hoped to publish an account of the further development of this work in the near future, but meanwhile the following selected illustrations of the more general application of this view may be cited.

Steric incompatibility between an *o*-methyl or -methoxy group and a dimethylamino group is reflected in an enfeebled mesomeric relationship of the latter group with the nucleus, as exhibited on one hand in a minimized tendency to *p*-substitution, for example, by nitrous acid, benzene diazonium chloride, formaldehyde, or benzaldehyde[3], and on the other, in predominating basicity of the *o*- over its *p*- and *m*-isomerides, which is in striking contrast with the relationships of the toluidines, their monoalkyl derivatives and 1.8 dimethyl 1.2.3.4 tetrahydroquinoline[4]. The abnormally slow alkaline hydrolysis of *o*- relative to *m*- and *p*-acettoluides[5] is similarly explained.

Reduced mesomerism of the carboxyl group is illustrated by enhanced acidity, greater activation energy of acid-catalysed esterification, and reduced activation energy of alkaline ester hydrolysis, in the case of *o*-toluic acid as compared with benzoic acid; *o*-tertiary butyl benzoic acid, again, is even stronger than *o*-toluic acid[6]. However, if a reaction involves orientations which are hindered by an *o*-substituent, this hindrance may partly reveal itself in an elevation of the activation energy representing an 'energy of orientation'. The conversion of 3-nitrophthalic acid into its 1-methyl ester by ordinary esterification, and of the anhydride into the 2-methyl ester by treatment with methyl alcohol[7] are interesting illustrations of the principle just discussed. *O*-tolylphenylchloromethane[8] shows, as expected, a greater 'ortho effect' than does *o*-methylbenzyl chloride[9] in acid hydrolysis. The phenyl boric acids[10] and the phenols[11] show no 'ortho effect' because hindered mesomerism is out of the question in each case owing to absence of mesomerism and steric orientation respectively.

In general, only monoketonic derivatives are produced from benzene and its homologues by the Friedel-Crafts reaction, yet di-*o*-alkyl substituted aryl ketones, and these alone, are amenable to further substitution under these conditions[12]. This is the more striking in view of the fact that mesityl methyl ketone combines exothermally with aluminium chloride; the consequent deactivation is, however, not transmissible to the nucleus owing to the steric conditions. The same factor may well be operative in determining the extraordinarily facile dinitration of mesitylene. Similarly, it must be expected that the *o*-nitrothiophenoxide ion is a more nucleophilic reagent than the *p*-isomeride, while *p*-nitrochlorobenzene is more reactive to such reagents than its *o*-isomeride.

There are numerous examples of carbonyl attached to an aromatic nucleus undergoing hydrolytic fission with acids[13]; almost without exception, an *o*-substituent is a necessary condition. This 'ortho effect' probably has a two-fold origin: (*a*) the previously discussed steric hindrance of mesomerism ($-T$) of the carbonyl group; and (*b*) steric promotion of the polarization in the nucleus which allows a displacement of a nuclear attached atom out of the plane of the nucleus to relieve the crowded orientation. Both these steric effects facilitate electrophilic attack.



In α-tetralone, on the other hand, the atoms in question are coplanar with the nucleus, and in consequence hydrolytic fission and inter- and intramolecular rearrangements with aluminium chloride are not observed.

Sterically enhanced nuclear polarizations no doubt facilitate such observed conversions as *iso*-durene and hexamethylbenzene into mesitylene with hydriodic acid[14]. The inter- and intra-molecular rearrangements brought about by aluminium chloride frequently find their origin in this twofold steric effect of *o*-substituents on mesomeric and electromeric effects.

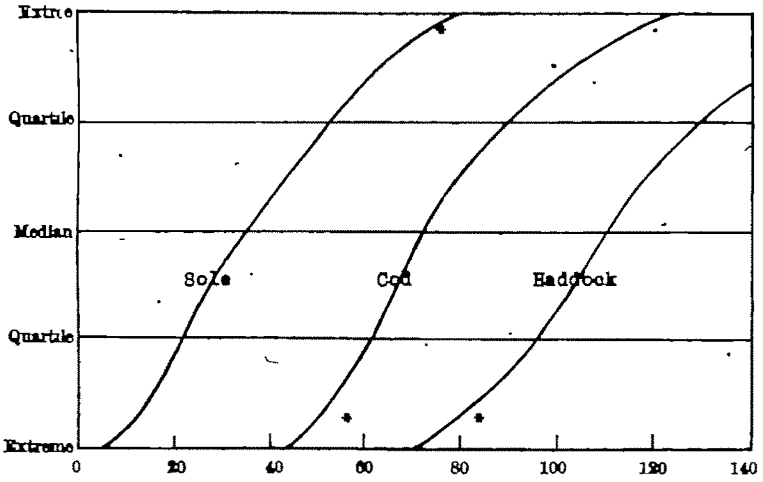
Fishery Statistics

When we compare the catch of fish of one year with that of another, we find one greater or less than the other, and that seems at first sight the end of the matter. But if we analyse each year's total into its monthly parts we see in every case a certain seasonal periodicity; and it follows that we may expect to find not only differences of total quantity, but also of phase and amplitude, the two ways in which one periodic function differs from another. Let us reduce the monthly quantities to percentages of their annual totals, and then compare the periodicity of one year with another or with a mean. To show, briefly, how orderly and how instructive the rough market statistics are, let us merely compare one year's monthly data with another's:

Aberdeen Landings of North Sea Plaice; monthly percentages of annual catch

	Jan.	Feb.	March	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
1932 ..	7·7	9·5	8·4	9·9	7·9	8·7	7·4	9·4	9·7	9·3	7·2	4·9
1937 ..	3·3	3·6	3·9	6·2	6·8	7·7	9·2	14·5	17·5	11·4	8·8	7·1
Difference	4·4	5·9	4·5	3·7	1·1	1·0	−1·8	−5·1	−7·8	−2·1	−1·6	−2·2

The monthly discrepancies yield a nearly regular fluctuation, and show at a glance how the phase of the periodic function was accelerated in one year and retarded in the other.



North Sea Landings (Aberdeen): 1912–37
*** Catches of 1937.

While writing on this point let me mention another, though it is no more than a statistical gadget; I think it is new, and Mr. Udny Yule says it is new to him. We want to compare, say, last year's catch with twenty previous years, and not in order of time but of mere quantity. We take, as usual, the extremes, quartiles and median of the series; we shall find these five points enough to draw, approximately, a curve of distribution of the whole. It will obviously be an S-shaped curve; and we may mark it with an asterisk to direct attention to a particular year. The annexed chart thus shows at a glance how 1937 was all but the worst year for cod and haddock, and all but the best year for soles, in six-and-twenty years.

Symphyogenetic Development

There has existed a need for a term to express the idea of the interaction of hereditary and environmental factors in producing the development of an organism. It must be a term to signify that the organism is the resultant of the integration of the two sets of factors. It must convey the idea that has been almost universally accepted by writers in the field of development that the organism is always 'becoming something' and 'tending somewhither', because it is a result of an interrelation between an environmental milieu and hereditary potentialities which together constitute the necessary materials and conditions to produce a living thing through their interaction. The term *symphyogenetic development* seems to be suitable for expressing this idea.

Symphyogenetic is derived from the three Greek stems, σύν, meaning *with*, φύειν, meaning *to grow*, and γίγνεσθαι, meaning *to come into being* or *to be*. Literally, it conveys the idea of something coming into being and growing as a resultant of the interaction of two or more factors, and thereby undergoing development. The word symphyogenesis has had a previous usage. The "Century Dictionary and Cyclopedia" gives its meaning as follows, "In *bot.* the forming by union of previously separate elements". The "Webster's New International Dictionary" defines it thus, "*Bot.* Development of an organ by the union of previously distinct organs". The present proposed usage of symphyogenetic does not violate either of these definitions of symphyogenesis.

To define symphyogenetic in terms of its proposed use, where it is to be employed as a modifier of development, it would mean, *the combining of hereditary determiners and environmental factors to produce the characteristics manifested in an organism's structure and behaviour.* Symphyogenetic development would be used in contrast to maturational development, which emphasizes the ordering of the hereditary determiners for producing the sequential regularity of development, other things being equal. Its usage would be in contrast to epigenetic development, which emphasizes the production of differentiations in development as a result of the influence of environmental factors acting upon a relatively simple structure in the beginning. Obviously it is in contrast with the ancient idea of preformism.

Skin Cancer due to Handling Coal Tars Used for Preservation of Fishing Nets

COMPLAINTS that several fishermen had contracted cancer of the skin after handling tar used for the preservation of nets resulted in an interested firm submitting a sample of their tar to this department to investigate its carcinogenic effect on mice. This particular tar (our No. 7) was said to have been manufactured in a horizontal retort at a temperature of 1100° C. It was found to be highly carcinogenic for the skin of mice, 75 out of 100 bearing malignant tumours after bi-weekly applications of the tar for forty weeks. This result compared very unfavourably with a number of tars, used for various purposes, previously tested by us.

Later, three further tars from the same firm were submitted to us for test: (1) our No. 14, made in a vertical retort at 1390° C.; (2) our No. 16, as before but said to be cut back with light tar oils; (3) our No. 15, said to have been made from oil pitch and light tar oils.

Results of animal experiments showed that Nos. 14 and 16 were almost as carcinogenic for mice as No. 7. but that No. 15 was considerably less carcinogenic, only 17 mice out of 100 contracting skin cancer after forty weeks, although twenty of the mice survived for this period.

Preliminary tests with samples of creosote oil and anthracene oil revealed that both are carcinogenic for the skin of mice.

In our opinion, if gas tar as such is used for preservation of fishing nets, only that made in vertical retorts using a temperature as low as practicable should be used.

The Garner Principle of Co-operative Activation

IN a letter in NATURE of August 12, p. 287, Prof. W. E. Garner has made, in my opinion, a most important contribution to the advancement of physico-chemical science. It seems probable that the Garner principle will be of great value in the understanding and formulation of many catalytic phenomena, including the interlinked sets of reactions which are now known to occur in the operation of many enzymes and co-enzymes.

London, W.C.1.

Points from Foregoing Letters

L. H. Gray and J. Read, working on the biological effects of neutrons, have used the ionization produced in air in small graphite ionization chambers as a measure of neutron dose. Experiments have now been made which make it possible to correlate the ionization with the actual increment of energy per unit volume of tissue due to the recoil atoms generated by the neutrons. Calculations based on interaction cross-sections agree with two different lines of experimental investigation in showing that a neutron beam which produces 1 E.S.U./c.c. of ionization in a graphite chamber will give the same energy absorption per unit volume of tissue as 7 roentgens of γ-rays (20 per cent).

M. Lecoin and I. Zlotowski have measured very carefully with an adiabatic microcalorimeter the mean energy of disintegration of radium E. They obtain the value 320,000 ± 5·000 ev., and the lower limit is regarded as very near the most probable value.

G. I. Jenkins and A. Norris describe a new method of measuring the thickness of built-up films on metal by finding the wave-length at which minimum intensity of reflected light occurs at constant angle of incidence. The method makes possible a measurement of the thickness of very small numbers of layers and seems especially promising in the field of protein investigation for which it was devised.

Surprise has often been expressed that Kepler failed to find the true law of refraction. R. A. Houstoun shows that Kepler's formula satisfies the observations that were available to him better than the modern formula does.

The spectrum of the N_2 molecule in the light of the night sky is well known to-day. The upper energy level of the most intense Vegard-Kaplan bands are $v = 2$ or 3; among the red bands of the first positive system, the band $B(v = 7) \rightarrow A(v = 4)$ is much the most intense. J. Cabannes and Rose Aynard try to explain that selection by resonance phenomena.

Evidence is brought forward by D. Keilin and T. Mann that carbonic anhydrase isolated from the red corpuscles of ox blood in a pure state is a zinc-protein compound.

P. Suomalainen has previously produced artificial hibernation by injecting magnesium and insulin into hedgehogs and transferring them into cold conditions. The quantities used, however, were so large that an equal amount of insulin alone killed the animals. The author has now decreased the amounts of injections, and artificial hibernation is brought about with insulin only and cold. Serum magnesium is considerably increased in the insulin hibernation, as in the natural hibernation.

G. Baddeley shows that the more general application of sterically hindered mesomerism is illustrated by strengths of acids and bases, velocities of side-chain reactions and nuclear substitutions, and by the hydrolytic fission of carbonyl attached to an aromatic nucleus. Steric promotion of nuclear polarizations is also considered a factor contributing to the 'ortho effect'.

Sir D'Arcy W. Thompson suggests that, as the catch of fish is a periodic phenomenon, it should be both useful and easy to take note of differences between one year and another in phase and amplitude as well as in the annual total. A new form of statistical chart is also suggested.

RESEARCH ITEMS

Cranial Deformation among the Ancient Maya

Two cases of artificial deformation of a remarkable and unusual character have been described by A. J. E. Cave (Smithsonian Institution, *Anthropological Papers, Bull.* 123; 1939). They were derived from Maya mounds in the Corozal District of British Honduras excavated by the late T. W. Gann. The first specimen is the mutilated brachycephalic cranium of an elderly subject, probably female, which lacks almost the entire facial skeleton. It has an auricular height of 111 mm., a maximum length (glabella-inion) of 150 mm., a maximum (biparietal) breadth of 165 mm., a minimum frontal breadth of 92 mm., and a cephalic index of 110. The whole calvaria is fairly symmetrical; but it is curiously and quite artificially deformed. Mechanical flattening of the supra-inial occiput has produced an enormous lateral out-thrust of the cranium in the mid-parietal transverse axis. The frontal region has not been directly compressed and merely shares in the general lateral bulging of the whole skull. In each temporal fossa there is an obvious and artificial groove ascending over the alisphenoid and anterior portion of the parietal to be lost above the superior temporal crest. These grooves must be the product of tightly applied bandages. In norma verticalis the cranium suggests an abortive 'bilobed' appearance. The cranium is actually of greater breadth than length. The same condition appears in the second specimen—the calvaria of an adult, middle-aged subject, presumably male. It is imperfect, and also partially a restoration, but enough remains to show that despite deformation it was brachycephalic and of corresponding type to Specimen I. Its measurements are auricular height, 100 mm.; length, 154 mm.; breadth, 171 mm., min. frontal breadth, 101 mm., cephalic index, 111. Artificial deformity has been produced by pressure applied to the supra-inial portion of the occipital, and the hinder portion of both parietals, resulting in a squashing forward of the vault and an enormous exaggeration of the biparietal diameter, which exceeds the maximum length of the skull. Two artificial grooves indicate the application of bandages. Like Specimen I, this skull also shows a tendency to the bilobed condition.

Tuberculosis among Young Adults in England

While the general death-rate from tuberculosis of the lungs has been steadily declining during the last 60–70 years, that for young men and women, aged 15–24 years, which followed the general trend during last century, has been almost stationary during this century. This set-back is particularly evident among young women, whose pulmonary tuberculosis death-rate per 100,000 fell from 276 to 112 in the thirty years between 1871–80 and 1901–03; but remained almost stationary in the next thirty years, being 107 in 1911–13 and again in 1931–33. This problem has been examined, so far as England is concerned, by P. D'Arcy Hart and G. Payling Wright, whose findings are set out in a recently issued report ("Tuberculosis and Social Conditions in England". National Association for the Prevention of Tuberculosis, London. Price 3*s*.) The phenomenon has been examined mainly in relation to social conditions, including general standard of living, housing, internal migration and volume of occupation. The retardation in decline of phthisis mortality has affected young women more severely than young men, and at present nearly half the deaths from all diseases among young women are due to phthisis. On the whole, urban areas are more seriously affected than rural districts. The unsatisfactory course of pulmonary tuberculosis among young adults seems to be due to a complex of factors. Unsatisfactory trends in the national standard of living, and the rapid industrialization of young women, appear to have played important parts, while bad local social conditions, in particular bad housing, have increased the effect in certain localities.

Anatomy of Apple Roots

The possibility of predicting the performance of apple varieties on different rootstocks is brought nearer by the observation that vigour is correlated with certain anatomical features of the stock roots. A. B. Beakbane and E. C. Thompson (*J. Pom.*, 17, 141; 1939) have examined sections of the roots of eighty-six four-year-old apple trees on Malling stocks VII and IX and on eight new clonal stocks worked with Lane's Prince Albert. A striking negative correlation was found between the relative area of bark to wood, as seen in transverse section, and the vigour of the scion. The percentage areas of fibres, vessels, rays and to a less extent, of parenchyma, estimated from photographic prints of sections, were found to be related to scion vigour. Vigorous rootstocks were found to have an almost equal amount of living and dead tissue, whereas the dwarfing stocks had twice to three times as much living as dead tissue, that is, more parenchyma and ray cells. The vigorous stocks had a larger number of vessels and nearly twice as many xylem fibres as the dwarfing stocks and there was a tendency for the vessels to be larger in the vigorous stocks. If the tendency thus observed persists in older trees, examination of internal structure may enable breeders to classify new rootstocks according to vigour without the lengthy field trials now necessary.

Spraying and Photosynthesis

The application of a spray fluid for the control of insects or fungi has usually been regarded solely from the pathological point of view. R. A. Hyre has shown, however (Cornell Univ. Agr. Exp. Sta. Memoir 222, Ithaca, N.Y., April 1939), that certain sprays lower the photosynthesis of the plant to which they are applied. Lime-sulphur may even reduce it by as much as 28 per cent at ordinary summer temperatures, but Bordeaux mixture, on the other hand, has little effect. Emulsified sulphur pastes were found to be intermediate in their effect upon photosynthesis. Respiration was not markedly affected by spray fluids. Studies upon such factors as the biennial bearing of tree fruits show that these plants cannot sustain any considerable loss of photosynthesis with impunity. The loss in anabolism through spray applications is not of many days' duration but it is likely to occur at the critical time of flower bud formation, when the extent of the subsequent year's crop is being determined. The use of Bordeaux mixture instead of lime-sulphur in the summer spray programme would provide a practical means for the achievement of pathological control without physiological disturbance.

Narcissus Mosaic

A LEAF-MOTTLING virus disease of narcissi has been known for some considerable time, but details of its etiology and physical properties have only recently appeared ("Studies on Narcissus Mosaic" by Frank A. Haasis, Cornell Univ. Agr. Exp. Sta. Memoir 224, Ithaca, N.Y., U.S.A., April 1939). Affected plants are stunted, they bear inferior bloom and produce poor bulbs. Their foliage and flower stems are mottled by yellow stripes, whilst the flowers are occasionally distorted and streaked with white, though symptoms vary with the variety. Transmission to a healthy plant can be effected by grafting a portion of a diseased bulb, by the normal vegetative propagation, and by various mechanical means, but neither by root contact nor through soil contamination. The virus appears to be of moderate virulence, its resistance to ageing *in vitro* is slight, it can withstand but little dilution and it is inactivated by a temperature between 70° and 75° C. Control presents the difficulties usually associated with virus diseases, and little can be done beyond the removal of infected plants, and the growth of selected stock within insect-free cages.

'Packet Velocity' of Dispersive Elastic Waves

K. Sezawa and K. Kanai have recently discussed this problem (*Bull. Earthq. Res. Inst., Tokyo*, 17, Pt. 2, 208–232; 1939). The basis of the discussion was a wide range in wave-length of Rayleigh and Love waves which could be adapted to an extensive range of dispersion conditions of waves of irregular form. From a mathematical investigation of the chosen examples it was ascertained that even should the wave form be irregular, the energy of the waves was transmitted with a special group velocity. If the sinusoidal components composing the irregular waves had different group velocities, it appeared likely that the centroid of the wave energy, that is, the centroid of the energy of the wave packet, would be transmitted with the group velocity that corresponded to the waves of infinite length involved in the irregular waves. If the group velocity differed with difference in length of the sinusoidal waves, even should the disturbance be of sine form of finite extent, the centroid of the same disturbance was still transmitted with the group velocity of sinusoidal waves of infinite length. If the dispersion formula was of the form $c = A \pm Bf^n$, the centroid of a packet of irregular waves was transmitted with velocity A, that is, the group velocity of the longest possible waves composing the wave packet.

Fluidity and Temperature

A SIMPLE relation between fluidity (θ) and absolute temperature (T), namely, $\theta/T = a + bT + \ldots$, has been established by E. C. Bingham and S. D. Stookey (*J. Amer. Chem. Soc.*, 61, 1625; 1939) for a large number of liquids, apparently failing only for alcohols. It has also been shown to apply to some types of solutions. It is found that the constant a is a function of the homologous series to which the compound belongs, and the constant b a function of the molecular weights of the members of the series, so that an equation may be obtained containing constants which are functions only of the series concerned, and not of individual members of the series, namely, $\theta/T = A_s + \alpha T 10^{(\beta/M - \gamma/M^2)}$, where M is the molecular weight and α, β and γ are constants. It is thus possible to calculate the viscosity of any member of a non-associated series up to ten carbon atoms at any temperature by means of only four constants.

Structure of Cyclo-Octatetrene

The evidence for the structure of 1,3,5,7-cyclo-octatetrene, discovered by Willstätter and Waser in 1911 and widely used in discussions concerning the structure of the aromatic nucleus, rests chiefly on its mode of synthesis from pseudo-pelletierine and on its hydrogenation to cyclo-octane. C. D. Hurd and L. R. Drake (*J. Amer. Chem. Soc.*, 61, 1943; 1939) have now prepared both 1,2- and 2,3-butane-*bis*-(trimethylammonium) bromides from pure specimens of 1,2-dibromobutane and 2,3-dibromobutane. Pyrolysis of the *bis*-quaternary hydroxide from the 1,2-salt gave rise to ethylacetylene and methylallene, but no 1,3-butadiene. Pyrolysis of the *bis*-quaternary hydroxide from the 2,3-salt yielded 1,3-butadiene and methylallene (or methylallene and dimethylacetylene), the latter being slightly in excess of the 1,3-butadiene. The assumption of the former authors that conjugated unsaturation results exclusively during pyrolysis of a functional group in the quaternary hydroxide molecule is unjustified and the fact that 1,3-butadiene was not the exclusive product from 2,3-butane-*bis*-(trimethylammonium) hydroxide is regarded as casting serious doubt on the structure of Willstätter's cyclo-octatetrene and on the conclusions drawn from it.

A Possible Explanation of Very Slow Adsorption

IN a series of papers published during the last four years (*Curr. Sci.*, 4, 405; 5, 645; 6, 446; 7, 182; *Proc. Ind. Acad. Sci.*, 4, 97; 1936: *Kolloid-Z.*, 84, 138; 1938: 86, 205; 87, 272; 1939), K. S. Gururaja Doss describes further experiments showing that the rate of adsorption and lowering of surface tension, in aqueous solutions of various colloidal electrolytes, is frequently very slow. This slow accumulation at the surface, which had been previously observed with paraffin chain salts in dilute solution, is now explained as due to the existence of a potential energy barrier at the surface, caused by the electrostatic repulsion exerted by the electrolytically dissociated end groups of those molecules which first arrive at the surface, on the similarly charged end groups of other molecules attempting to diffuse to the surface. Only those molecules, therefore, which possess unusually large kinetic energy can pass this barrier; but once arrived at the surface, their hydrophobic portions retain them at the surface. To such molecules travelling towards the surface, an energy 'hump' must be surmounted, in order that the charged end group may pass through the diffuse double layer set up by the molecules first adsorbed; once this is passed, the molecules find an energy 'trough' at the surface, caused by the natural tendency of the hydrocarbon portions of molecules to cover the surface of water. Consequently a considerable energy of activation is likely to be required for the adsorption of molecules containing electrolytically dissociated end groups, and some hydrocarbon, in their constitution, and this may account for the slow adsorption.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

LIÈGE MEETING

IN response to the kind invitation of the University of Liège, the French Association for the Advancement of Science met during July 17–22 for the third time in Belgium; the previous meetings were at Liège in 1924 and at Brussels in 1932.

The International Water Exhibition at Liège which marked the inauguration of the Albert Canal gave the meeting a special interest. Prof. C. Fabry, president of the French Association, presided over the meeting, and Prof. Dehalu, *administrateur-inspecteur* of the University of Liège, was president of the local committee.

The opening ceremony took place on July 17 in the hall of the University. Prof. Dehalu expressed his pleasure at receiving the Association at Liège for the second time, and Senator Buisseret, speaking on behalf of the burgomaster, welcomed the members of the congress. Prof. C. D. Ellis, Wheatstone professor of physics at King's College, London, representing the British Association, and Dr. C. Romaña, representing the Argentine Association for the Advancement of Science, brought messages of good will for the success of the meeting. Prof. Fabry, after having expressed the thanks of the Association to the local committee at Liège, delivered his presidential address, on interstellar space.

Prof. Fabry showed how a profound study of the light of the stars has enabled us to detect, in interstellar space, matter in a state of extreme rarefaction (1 kgm. nearly in a volume equal to that of the earth). In addition to matter, there exists also in interstellar space energy in the form of radiation emitted by the stars. These results have demonstrated the fruitfulness of collaboration of diverse scientific disciplines and of pure and applied science. Such collaboration is also the object of the French Association and of similar bodies.

The scientific meetings were held in the magnificent Institutes of Civil Engineering and Chemistry of the University of Liège at Val Benoît on July 17 and the following days. July 19 was devoted to an excursion on the Albert Canal and to a visit to a colliery at Beeringen. July 21, the day of the national fête of Belgium, was taken up with a visit to the Water Exhibition.

The several sections of the Association showed great activity. The question of water occupied a prominent place in the programme, and was the subject of the following papers: M. Wyart, the states of solid and liquid water studied by X-rays; M. Cabannes, the Raman spectrum of liquid water; M. Kraft de la Saulx, history of the construction of hydraulic machines; M. Tongas, thermodynamic properties of steam; M. Trochon, microphysics of mists considered as aerosols; M. Roulleau, hygrometry; M. Rocard, kinetic theory of liquids; M. Hubault, pollution of waters, their industrial utilization and modifications of their fauna.

The Section of Civil and Military Engineering, under the presidency of M. Campus, was divided into three subsections: theoretical and applied hydraulics; navigable channels and ports; hydraulic works. One session was devoted to colonial hydrography.

The Section of Physics heard communications, among others, from Profs. F. Joliot and F. Perrin. The work of the Section of Geology was completed by field excursions; the Section of Botany also had excursions in which the Royal Society of Botany of Belgium and the Liège Botanical Circle joined.

The Sections of Biogeography and of Zoology held several joint sessions, with papers on the biology of equatorial lakes (M. Damas), the relations between the internal and external media in aquatic animals (M. Florkin), and the phreatic fauna (M. R. Leruth).

Mention should also be made of the communications presented to the Section of Geography (streams, their utilization and management, demographic and social aspects of water); and to the Sections of Medical Sciences (metabolism of water), of Psychology and Pedagogy, of Radiology and of Odontology.

Special subsections considered technical applications of water, applications of electricity, archæology and folklore.

The communications presented at the meeting will form a special volume published in connexion with the Liège meeting.

The French Association will meet in 1940 at Nice, some time in July, under the presidency of Prof. Pieron, professor at the Collège de France, and director of the Institute of Psychology of the University of Paris.

SOCIAL AND INTERNATIONAL RELATIONS OF SCIENCE

THE first annual report of the Division for the Social and International Relations of Science of the British Association, founded by resolution of the General Committee of the Association in August 1938, was presented at Dundee and is printed with the Report of Council of the Association.

A statement of the aims and objects of the Division, together with a request for information on any work in the field of social relations of science, was circulated to some three hundred and fifty associations, institutions and learned societies in the British Isles and abroad. The replies received indicated that much work of this nature has been done, or is in progress, and in certain instances opportunity has already been found for the Division to exercise its function of co-ordination. Many offers of co-operation were received from bodies particularly interested in the social impacts of science, and several valuable contacts have been made. Notably, the Division learned that P E P (Political and Economic Planning) proposed to prepare a report on the organization of research in Great Britain, but was hampered by lack of funds to start the work. The Council of the Association, at the instance of the Divisional Committee, voted £100 as salary for the research worker appointed by P E P to collect the factual material. This enabled the work to proceed immediately, pending the acquisition of funds to maintain the inquiry from other sources. The necessary support has since been obtained from the Leverhulme Trustees, who have made available sufficient funds to carry on the inquiry until the autumn of 1940. The Division is represented on the committee supervising the work and will be associated with the report to be published in due course.

Some of the topics submitted to the Division for attention were referred to sections of the Association, and as a result several discussions and papers were arranged for the Dundee meeting.

A number of sub-committees have been appointed to deal with specific aspects of the Division's activities. One of these is considering the desirability of supplementing existing national research organizations whether in normal circumstances or in times of emergency. With the view of ascertaining details concerning systems of controlling and distributing grants in aid of research in other countries, an inquiry was directed to correspondents in the United States, France, Belgium, Holland, Denmark and the Dominions. Memoranda have been prepared by Prof. A. C. G. Egerton, and by Prof. J. D. Bernal and Dr. Julian Huxley, respectively, dealing with expenditure of public funds on research and discussing the question of a Research Co-ordination Council.

The sub-committee on nutrition and agriculture was responsible for a meeting at Reading to discuss milk in its nutritional and allied aspects. A resolution put forward from this meeting to the Council of the Association runs as follows:

"In view of the proved danger of the spread of epidemic and other diseases by the consumption of raw milk, of the efficiency of controlled pasteurisation in abolishing this danger and of the slight damage to the nutritive and other properties of milk caused by effective pasteurisation, it is essential for the national health that it be made compulsory in all urban areas with a population of 20,000 or more to pasteurise effectively all milk before sale to consumers to ensure its safety and to assist in securing that increase in the *per capita* consumption of liquid milk which is essential for improvement in the national level of nutrition." The Council, after consideration and consultation with the Nutrition Sub-Committee, considered it desirable that before taking any action on this resolution, a factual report on the whole question of the pasteurisation and sterilization of milk should be procured, and steps are being taken to do this.

Other sub-committees have been appointed to consider the economic requirements of nations, the influence of scientific and technical developments on industry, and on social psychology.

A Finance Sub-Committee made a recommendation to the Council of the Association that consideration should be given to the desirability of an appeal for funds to (*a*) private individuals and firms, (*b*) trusts at home, (*c*) trusts abroad, (*d*) H.M. Government. The Council adopted this recommendation, with the provision that of these possible sources, the first-named should be first explored.

Meetings arranged by the Division were held during the past year at the University of Reading, in London at the Royal Institution, and at the University of Manchester.

RADIO EXHIBITION, OLYMPIA

THE exhibition of radio apparatus organized annually by the Radio Manufacturers' Association was opened at Olympia on August 23 and is remaining open each weekday until September 2. This year's exhibition was conspicuous for the greatly increased attention and interest devoted to television receivers and also to several somewhat novel features which had a strong appeal to the more technically minded members of the public.

As regards the general display of sound broadcasting receivers, no fresh and outstanding change in technical design was in evidence this year. The large variety of models shown indicated that manufacturers have devoted attention for once to a steady improvement in efficiency and reliability, and the listener who is more concerned with service than with novelty may be assured that he can buy a new set with complete confidence. Most manufacturers now supply some form of 'push-button' tuning selection as part of one of their standard designs. A notable increase in the number and variety of portable receivers shows that there is a maintained demand for this type, and an innovation this year is the portable receiver operated entirely from dry batteries. This is the result of the introduction during the past year of new types of valves with a very low filament current consumption, so that a complete receiver may be operated under normal average conditions for several months, without changing or re-charging batteries.

It was in the field of television that the most marked change was evident in this year's exhibition of receivers. Most manufacturers' are now in a position to supply several types of television receivers, and these range from the table model with a small although very clear picture, up to an imposing cabinet model with a picture size about 24 in. × 18 in. In all cases frequent daily demonstrations were given on the manufacturers' stands, while, in addition, a specially arranged 'television avenue' enabled the visitor to inspect some fifty different models in operation on the same programme and so judge their relative merits. Considering that, so far, television reception is limited in Great Britain to the programmes radiated from the one station at Alexandra Palace, the prospective purchaser of a receiver was very well catered for at the exhibition.

Among the conspicuous features of the layout of this year's show were the uniform flat-roofed stands, and also the models of Broadcasting House and the

Alexandra Palace tower at opposite ends of the main hall. The B.B.C. provided several technical exhibits, including a television studio and control room in operation. A sound-recording van, complete with studio and associated apparatus, a motor-car fitted up for film recording purposes, and the 80-ft. telescopic aerial of the mobile television unit were also part of the display provided by the B.B.C. The Post Office demonstrated apparatus used for short-wave radio telegraph and telephone purposes, and illustrated the various stages in the dispatch and receipt of telegrams. Other novel features included technical exhibits by the radio departments of the services, such as field equipment as used by the Royal Corps of Signals, a replica of the wireless office of a destroyer by the Royal Navy, and a layout of the various electrical and radio equipment of aircraft by the Royal Air Force. An interesting and popular feature on the stand of the latter service was a 'link trainer', designed to represent the cockpit of a modern aircraft. It contains all the controls and equipment of a real cockpit, and with it all conditions of flying can be simulated on the ground. The exhibit was used to demonstrate the manner in which a pilot may fly in fog or at night, navigating entirely with the aid of wireless instruments receiving signals from beacons on the ground.

Reverting to the manufacture and production of ordinary broadcasting receivers, a number of firms had contributed to the model factory which was set up in the exhibition. Various stages in the assembly and production of receivers or their components were shown in full operation under normal factory conditions. In addition, the various stages in the assembly of several manufacturers' standard receivers were shown on a rotating drum model in continuous operation. This section of the exhibition was designed not only to interest the technical enthusiast but also as an attempt to induce the ordinary listener to learn something of the internal construction and mode of operation of his receiving set.

Altogether, the exhibition demonstrated a successful attempt on the part of the organizers to make a wider appeal to the broadcast listening public, and it was extremely unfortunate that it was held during a period of such acute international tension.

R. L. S.-R.

DENTITION OF AUSTRALOPITHECUS (PLESIANTHROPUS)

A COMPARATIVE and phylogenetic study of the dentition of the extinct South African man-ape *Australopithecus* (*Plesianthropus*) *transvaalensis* Broom has been made by W. K. Gregory and Milo Hellman, who visited South Africa in 1938 at the invitation of Dr. Robert Broom and Prof. Raymond Dart to examine the evidence at first hand for this purpose (*Annals of the Transvaal Museum*, 19, 4; 1939).

One of the most astounding features of the type *A. transvaalensis* is the combination of a natural braincast, which is somewhat smaller than that of a large gorilla, with a dentition of almost human appearance. According to the experience of palæontologists the material available, though insufficient to satisfy statistical requirements, is adequate for determining the systematic position of Plesianthropus among the higher primates; and it is affirmed with Broom that in South Africa there once lived apes which had almost become men.

In the female Plesianthropus the premaxillary prognathism is much more pronounced than in the Ramapithecus from the Siwalik Hills, though the latter is a much smaller and more delicately built form. As compared with Sinanthropus the premaxillo-maxillary regions of Plesianthropus are more prognathous. Likewise in the lower jaw, the available evidence indicates that the forepart of the jaw in Paranthropus was shorter and more retracted than in the apes, and was approaching the stage of Sinanthropus. In this respect Paranthropus was structurally intermediate between the existing apes and primitive man. The excessive thickness of this jaw and the extreme flattening of the facial plate are unique characters, which though by no means excluding Paranthropus from the dryopithecine stock, are conspicuous differences from Sinanthropus and other hominids, and tend to justify Dr. Broom's choice of the name Paranthropus as indicating a side branch of the pre-human stock.

Turning to the evidence of the teeth themselves, the upper central incisor of Plesianthropus is unknown, but indications point to a derivation from certain conditions present in Siwalik dryopithecines, and from this stage the Sinanthropus-Mongoloid series (with extreme shovel-shaped first and second incisors) is derivable merely by further emphasis in the same direction. In modern man further emphasis of the method of growth produces peg-like crowns, while an emphasis on the basal swelling sometimes produces results observable in Palæanthropic man and some modern apes. Hence in respect to the stage of evolution of the upper permanent incisors Plesianthropus was intermediate between the ancestral dryopithecine stock and the primitive palæanthropic man; and it was more primitive than most modern anthropoid apes.

In regard to the canines Plesianthropus, starting from a primitive dryopithecine stage, was again approaching human conditions in the form and relations of its upper and lower canines. The small size of the canine teeth favours the conclusion that the small size of the canines in modern man is due to a secondary reduction. The lower canines are closer to Sinanthropus than to Sivapithecus. The edge-to-edge bite of upper to lower canines is again a primitive hominid condition, though occurring occasionally in old, very much worn, ape teeth.

In all the features of the premolars Plesianthropus was again intermediate between the primitive dryopithecus and the early human stage. Its upper premolars are more primitive than those of Sinanthropus in having lower, less taurodont, crowns and divergent buccal and lingual roots.

The molars, both upper and lower, in the South African fossil man-apes are unusually large, being exceeded only by *Sivapithecus giganteus* and by male gorillas. They differ, however, from those of gorilla, chimpanzee and other modern apes by certain easily recognizable peculiarities. In several respects their pattern has progressed towards the primitive human stage. It is not improbable that the great size of the third upper and lower molars was only a temporary phase preceding the reduction of these teeth in man.

The evidence from the Taungs infant is completely concordant with that of the Sterkfontein and Kromdraai adults, namely, that there lived in the upper Pleistocene of South Africa a group of small-brained man-apes that were derived from the widespread dryopithecine stock and were the less progressive cousins of man.

EIGHTH INTERNATIONAL CONGRESS OF REFRIGERATION

PLANS are being made to hold an international refrigeration congress at Cologne and Berlin during July 1–6, 1940. These congresses are held at intervals of about four years under the auspices of the International Institute of Refrigeration, which was set up by an international convention in 1920 and is supported by the majority of the nations.

After the Hague Congress in 1936, the scientific and technical side of the work of the International Institute of Refrigeration was reorganized and the control of that work entrusted to seven commissions, under a technical board composed of the presidents of the commissions dealing with various aspects of refrigeration. The reorganization became effective in 1938, when meetings of the commissions and technical board were convened in the rooms of the Royal Society. A one-day Conference on Refrigeration was also held following these meetings, and at this conference a number of papers were read which had been selected to embrace topics of especial interest to refrigerationists.

On July 14–16 last, similar meetings were held at Baden Baden and Karlsruhe, Germany. At the meetings of the technical board, a draft programme for the 1940 Congress was outlined.

On July 15, a Conference on Refrigeration took place at the Technical University at Karlsruhe, which has a department dealing with the engineering and physical side of refrigeration. In the grounds of the University is situated the Reich Institute of Foodstuff Preservation which is under the Ministry of Agriculture.

At the Refrigeration Conference four papers were read. Georges Claude dealt with the production and utilization of krypton. He indicated the advantages of the use of krypton for filling incandescent lamps, and stated that the production must be a separate field of activity rather than a by-product from liquid oxygen. G. Maiuri described machines working on the absorption principle and diffusing the refrigerant vapour in an inert gas. He stated that it is possible to attain temperatures below – 100° C. Ezer Griffiths dealt with various forms of hygrometers adapted to meet special requirements, and with humidity control. R. Plank dealt with air-conditioning in deep mines.

The meetings of the Technical Board were attended by representatives of various nationalities, and at the Refrigeration Conference there was a good attendance of German refrigerationists.

THE CAUSATION OF APPENDICITIS

APPENDICITIS is an inflammation around the cæcum, involving the vermiform appendage, and frequently associated with perforative ulceration. Previous to 1900, the disease was generally described under the names 'typhlitis' and 'perityphlitis'. The modern term 'appendicitis' began to be used in America between 1890 and 1900, and as a cause of death it first appears in the Registrar-General's annual report for 1901.

The immediate cause of appendicitis is a bacterial infection, but although the disease is a common one, the causes that predispose or precipitate an attack still remain but little understood, though stagnation of the intestinal contents in the appendix resulting in the formation of hard concretions is probably an important factor in many cases. There is a certain amount of information which suggests that habits of life, and in particular dietary habits, are of importance in predisposing to the disease.

In an endeavour to elucidate the causation of appendicitis, Dr. Matthew Young and Mr. W. T. Russell have surveyed the mortality statistics of Great Britain and of other countries and the statistics of certain hospitals, and their report is now published ("Appendicitis: A Statistical Study". Medical Research Council, *Special Rep. Series*, No. 233. H.M. Stationery Office. 1*s*. net). The figures relating to the frequency of appendicitis confirm that it is very prevalent and that it has been on the increase in recent years. Another point brought out is that the mortality in the highest social class is at least two and a half times greater than in the poorest social class, although the majority of diseases, especially those involving bacterial action, are commoner among poorer people. A curious feature of the mortality rates from appendicitis in women is that the figures strongly indicate that the mortality is greater among single than among married women.

The suggestion has been made that the nature of the diet may have an influence in predisposing to appendicitis, either an excess of food or possibly certain types of food, and both of these factors are probably more common among the well-to-do. The taking of purgatives or laxatives is another cause suggested, and this practice is probably more common in the higher social class and among women. No data bearing on these factors were obtained, though it is significant that the mortality from appendicitis in females fell during the war years 1915–18, when food restrictions were imposed, and increased afterwards

THE BRITISH ASSOCIATION, 1839

On September 7, 1839, the *Athenæum* said: "The Birmingham Session of the British Association closed its peaceful labours on Saturday, and the many distinguished persons who had there met in furtherance of one common object—the advancement of science, and the good of all mankind—are already scattered far and wide, not less content, we hope, because a leading political journal has been pleased to pour out on them its vials of wrath and scorn—how justly, our readers can now determine. . . ."

The meeting had been presided over by the Rev. William Vernon Harcourt (1789–1871), a son of Edward Harcourt (1757–1847), archbishop of York, and the father of Sir William Harcourt (1827–1904), the statesman. Harcourt served in the Navy for five years before entering Christ Church, Oxford. Taking holy orders in 1811, he held various ecclesiastical appointments in Yorkshire, and in 1824 was elected F.R.S. He took an active part in the founding of the British Association, was the first general secretary, and at the inaugural meeting gave an address in which he said: "I propose to you to found an Association including all the scientific strength of Great Britain, which shall employ a short time every year in pointing out the direction in which the researches of science should move, in indicating the particulars which most immediately demand investigation, in stating problems to be solved and data to be fixed, in assigning to every class of mind a definite task, . . . I am not aware that in executing such a plan we should intrude on the province of any other institution. Consider the difference between the limited circle of any of our scientific councils . . . and a meeting at which all the science of these kingdoms should be convened, which should be attended by deputations from every other society, and in which foreign talent and character should be tempted to mingle with our own. With what a momentum would such an Association urge on its purpose; what activity would it be capable of exciting."

A great part of Harcourt's presidential address in 1839 was devoted to the Antarctic Expedition and magnetic observations, but towards the end, he said: "The system of your meetings, Gentlemen, has brought together things which ought never to be disjoined—the principles of science, with their application to human use. After gathering your first members from our ancient schools of learning, you passed to the marts of commerce, and are now come to the heart of the manufacturers of England, and look around on all the resources and creations of mechanical art. The theorist and the mechanician here meet together to the mutual advantage of both; witness on the one part the instrument now working in the Philosophical Institution of this town, and almost supplying the place of a constant observer, which is about to measure the force of the wind at every instant of time, at St. Helena, the Cape of Good Hope, Van Dieman's Land and near the South Pole. But here I would not go further than the immediate vicinity of this town for an instance, the most striking on record, of the mighty influence which the introduction of a new principle in science an exercise on all the arts of life; the history of the improvement of the steam engine by Watt fully illustrates this truth. . . ."

FORTHCOMING EVENTS

British Association for the Advancement of Science (Dundee Meeting).

Sunday, September 3

At 8.30 p.m.—Sir Richard Gregory, F.R.S.: "Contacts of Religion and Science" (Division for Social and International Relations of Science).

Monday, September 4

At 10 a.m.—Dr. C. H. Desch, F.R.S., Dr. A. G. G. Gwyer, Prof. A. von Zeerleder, W. C. Devereux: "Light Alloys" (Discussion: Section B).

Dr. G. P. Douglas, Dr. A. Busemann, Dr. J. W. MacColl, C. N. H. Lock: "Problems of High-Speed Flight" (Discussion: Section A).

Prof. W. M. H. Greaves, Prof. R. W. Ditchburn, Dr H. R. Hulme, Dr. D. Chalonge, Dr. R. v. d. R. Woolley: "Surface Temperatures of Stars" (Discussion: Section A†).

Prof. H. H. Read, F.R.S.: "Metamorphism and Igneous Action" (Section C: Presidential Address).

Prof. L. M. Fraser, Prof. A. G. B. Fisher, R. L. Hall: "The Economics of Socialism" (Discussion: Section F).

Prof. R. A. Fisher, F.R.S., Dr. D. C. Wilson, D. M. Lubbock and Dr. I. Leitch: "Nutrition and Physique" (Joint Discussion: Sections H and I).

T. Thomson, Dr. R. Melville: "Seed Provenance, Local Races and Breeding of Forest Trees (Joint Discussion: Section K and K*).

T. M. Herbert, Dr. W. G. Radley: "Aspects of Industrial Research" (Discussion: Section L).

M. Jones, Dr. S. J. Watson, E. J. Roberts and Prof. W. Kerr: "Grass Conservation" (Discussion: Section M).

R. S. Finlow, J. K. Eastham, J. R. Walker, A. King, W. E. Billinghame, J. K. Anderson: Second Special Session on Jute.

At 11.15 a.m.—Prof. W. McClelland, W. A. F. Hepburn: "Recent Educational Research in Scotland" (Discussion: Section L).

At 2.15 p.m.—Prof. F. G. Baily, Sir Robert Robertson, F.R.S., Dr. R. W. Butcher, W. Malloch: "River Pollution" (Discussion: Conference of Delegates of Corresponding Societies).

At 3 p.m.—Prof. G. Murray, Prof. F. G. Donnan, F.R.S., Dr. J. S. Huxley, F.R.S., Prof. G. Dahlberg: "International Intellectual Co-operation" (Discussion: Division for Social and International Relations of Science).

At 6.30 p.m.—Dr. H. W. Melville: "New Lamps for Old" (Popular Lecture).

Tuesday, September 5

At 10 a.m.—Prof. M. Born, F.R.S., Dr. Ezer Griffiths, F.R.S., Dr. W. H. Hatfield, F.R.S., W. J. Todd, Dr. R. W. Powell, J. H. Awbery, Prof. J. Satterly: "High-Temperature" (Discussion: Section A).

Dr. E. V. Appleton, F.R.S., H. W. Newton, A. D. Thackeray, Prof. L. Vegard, Prof. W. M. H. Greaves, Prof. F. J. M. Stratton: "Solar and Terrestrial Relations" (Discussion: Section A†).

Prof. A. McKenzie, F.R.S. and Dr. R. Roger, Prof. M. Tiffeneau, Dr. S. F. Birch, Dr. A. K. Mills, Dr. T. S. Stevens: "Intramolecular Change involving the Migration of Groups" (Discussion: Section B).

Prof. H. O. Meredith: "Rates and Taxes" (Presidential Address: Section F).

Prof. D. Burns, Dr. I. H. Pearse, Prof. E. P. Cathcart, F.R.S.: "The Assessment of Physical Fitness" (Discussion: Section I).

R. Knight, J. L. Hardie, Dr. R. H. Thouless, Dr. C. A. Mace: Training the Mind" (Discussion: Section J).

Miss L. Grier, J. B. Frizell, A. E. Henshall, D. E. Collier: Discussion on the Spens Report (Section L).

T. A. Wedderspoon, Dr. G. Cockerham, Dr. T. McIntosh: "Seed Potato Growing" (Discussion: Section M).

At 10.30 a.m.—Dr. M. Macgregor, Dr. W. Q. Kennedy, Prof. G. Hickley, F.R.S., Prof. T. N. George, Prof. W. T. Gordon, Dr. T. S. Westoll: "The Boundary between the Old Red Sandstone and the Carboniferous" (Discussion: Section C).

At 2 p.m.—Colonel R. B. Campbell, Miss H. Drummond, Prof. A. Hemingway and H. R. Noltie: "Physical Fitness" (Discussion continued: Section I).

At 3.30 p.m.—N. F. Sheppard, Prof. H. J. Fleure, F.R.S.: "Anthropology in Education" (Discussion: Section H).

At 8.30 p.m.—Dr. Isaiah Bowman: "Science and Social Pioneering" (British and American Association Lecture).

Dr. D. A. Spencer: "Some Aspects of Colour-photography" (Public Lecture).

Wednesday, September 6

At 10 a.m.—Sir John Orr, F.R.S., L. Harris, D. Lubbock, Prof. P. Sargent Florence: Discussion on Nutrition (Division for Social and International Relations of Science).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

RESIDENT ENGINEER (temporary) of a Small Arms Ammunition Factory at Cullane, Co. Clare—The Secretary, Department of Defence, Parkgate, Dublin, N.W.5 (September 8).

ASSISTANT LECTURER in the Mathematics and Physics Department—The Principal, Municipal Technical College, Halifax (September 8).

ASSISTANT TRANSPORTATION SUPERINTENDENT (Rolling Stock), Traction Branch of the Great Indian Peninsula Railway—High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting 1/30A) (September 15).

LECTURER AND CHIEF DEMONSTRATOR IN ZOOLOGY in the Victoria University College, Wellington, New Zealand—The Secretary, Universities Bureau of the British Empire, 88a Gower Street, W.C.1 (October 1).

GRADUATE LECTURER IN MECHANICAL ENGINEERING in the Royal Technical College, Salford—The Director of Education, Education Office, Salford 5, Lancs.

THE VOICE OF SCIENCE

ONCE more the burden of war is laid upon us. Once more, as in 1914, the cynical disregard of Germany for the rights of small nations has constrained the British people to take up arms in the cause of justice and fair dealing in international relations. The challenge of the German Reich has been accepted reluctantly, and with no illusions as to the nature of the glories of modern warfare, only after every effort to secure a peaceful but equitable settlement of the differences between Germany and Poland has failed. It has been accepted with full realization of the gravity of every implication of the decision. But in turning to war as the last resort, the British people has acted with a unanimity such as never before in its history, and with a grim determination that no effort shall be spared in the endeavour to ensure that the cause which it holds just shall prevail.

From 1914–18, the Allies opposed dynastic ambitions in the interests of the freedom of peoples. No longer were the people to be the pawns of the political intrigues of their rulers. The world, it was said, was to be made safe for democracy—words that now have a mocking ring. In 1939, the canker has sunk deeper. It is not merely political liberty that is at stake, though that too is jeopardized. It is the spirit of man.

In no previous war has science played so great a part as that which will be demanded of it in the struggle that is at hand. For a time, while the issue hangs in the balance, it is the duty of the man of science to lay aside his just misgivings whether the greatest force of the human intellect should thus be harnessed to the forces of destruction. For the moment, the interests of pure science as an intellectual pursuit and discipline must remain in abeyance. The energies, the abilities, and the knowledge of each and every individual with scientific training must be directed without remission to the service of the Allied cause. Nevertheless, the end to be attained, and the end which science should hold ceaselessly before the eyes of the Allied peoples, is not destruction, but a constructive ideal—to ensure in the future such conditions as will make possible the advancement of all the peoples of the world without discrimination, according to the status and the traditions of each, in the light shed by reason and scientific knowledge. To keep alive the aims of science in furthering the pursuit of truth in the universe and the relation of that truth to the developments of man's nature, without regard to tribal and racial distinctions, should be, indeed, must be, the ultimate function of the scientific thinker, whatever may be his more immediate preoccupations.

As to the form in which that ideal will find embodiment, at the moment, in the turmoil of initial operations, it is too soon to attempt a forecast; but that it is no idealist's dream is certain. The failure of the League of Nations as a political organization has cast discredit in the popular mind on such forms of international co-operation. Possibly the League of Nations came before its time, and this has obscured in the popular verdict the enormous value of its scientific work in the study of social and economic problems, and the progress which has followed, where the practical application of the solutions suggested has not conflicted with the trends of nationalist development. To extend the fields in which such co-operation between peoples may be applied is the task of the future, when the time comes, as it surely will, for reconstruction.

CENTRAL REGISTER OF SPECIALISTS

IN NATURE of April 8, reference was made to the formation by the Ministry of Labour, for war-time use, of a central register of those with scientific, technical and professional qualifications, and the scheme was recommended to the attention of our readers. The need has now arisen, but fortunately the Register has reached an advanced stage, due to helpful co-operation of a great many learned bodies and professional institutes, and the Committees of the Council which advises the Minister on the Register have been reviewing the position reached.

We are informed that, at the end of July, 86,000 names were on the Register as a whole; the scientific research part of the Register contained at that date 7,000 names. The cards completed by the volunteers are held at the Ministry of Labour classified under the scheme of classification approved by the Committees, and a duplicate set of cards in the research classifications is held by the Royal Society.

The immediate purpose of the Register, which is under the guidance of the Advisory Council and its Committees, is to meet demands in war-time for the services of scientific and other personnel made by Government Departments (who will draw upon the Central Register for all their demands for persons possessing these qualifications) and by other employers engaged on work of national importance. Enrolment is voluntary, as indeed is the whole scheme. The services of panels of the Committees of the Council will be available for the selection of candidates for submission to the posts offered. In making the submissions, regard will be paid to the importance of the work offered in relation to that on which the volunteer is already engaged. The question of remuneration will be a matter for settlement between the volunteer and the employer concerned.

The Register will be operated centrally, but in the event of war exigencies compelling regional operation in any area, regional panels, nominated by the Committees, will act on their behalf.

How far those enrolled on the Register will be called upon can only be a matter of conjecture, and no promise is given that any particular individual will, in fact, be required. Those enrolled on the Register need not be deterred from undertaking any of the forms of national service (consistent with the Schedule of Reserved Occupations), but where such undertakings will involve full-time service they are asked to notify the Central Register.

There can be no question that, in the war which is now on us, a great demand will arise for the resources of scientific knowledge available for defence, and this section of the Register constitutes an extremely useful part of the general organization which the Government has set up for national defence.

A separate register of teams of scientific workers which it may be desirable to keep intact during at least the earlier stages of war has been compiled by the Department of Scientific and Industrial Research, and close liaison is naturally being maintained between this register and the Central Register.

The section of the Register relating to scientific research is dealt with by the Scientific Research Committee of the Council, with Prof. A. V. Hill, one of the Secretaries of the Royal Society, as its chairman, and is made up as follows: Prof. C. G. Darwin (mathematics), Dr. E. V. Appleton (physics), Prof. J. C. Philip (chemistry), Prof. R. V. Southwell (engineering science), Dr. E. B. Bailey (geology), Prof. V. H. Blackman (botany), Prof. D. M. S. Watson (zoology), Prof. A. V. Hill (physiology), Prof. W. W. C. Topley (pathology), Prof. F. C. Bartlett (psychology), Mr. C. S. Wright (director of scientific research, Admiralty), Dr. H. J. Gough (director of scientific research, War Office), Dr. D. R. Pye (director of scientific research, Air Ministry), Dr. R. E. Stradling (director of scientific research, Home Office), Dr. A. Landsborough Thomson (Medical Research Council), Sir E. J. Butler (Agricultural Research Council.)

The Committee has the following sub-committees: (1) Bacteriology and Pathology, (2) Botany, (3) Chemistry, (4) Engineering Science, (5) Geology, (6) Mathematics. (7) Physics, (8) Physiology and Biochemistry (9) Psychology, (10) Zoology.

The method of compiling this section has already been explained in the article in NATURE referred to above. The response to the appeal made for volunteers has been the best of any section, and is extremely gratifying. The proportion of those qualified scientific research workers approached by the Royal Society who have offered their services in their professional capacity for work of national importance in the event of war was already, at the end of July, 88 per cent.; it is now greater.

The Committee with its Sub-Committees has made recommendations regarding the Schedule of Reserved Occupations as affecting science. It has also directed attention to the need for facilitating the entry of suitable scientific workers into special branches of the defence forces.

The cards of the volunteers in the ten sub-sections of this section of the Register have been carefully reviewed by the sub-committees with a view to the best possible use being made in war of the special qualifications and experience of each individual. A certain number of research workers within the various categories were earmarked, before war broke out, for service with research branches of the defence departments.

The Committee had placed great importance on the preliminary training of research workers for war work, and the defence departments are arranged this summer for preliminary instruction at experimental stations, etc., of volunteers.

In view of the prominent part which industrial chemistry will be called upon to play in war-time, reference may be made to the Industrial Chemistry Section of the Register. The Committee advising on this Section of the Register has as its chairman Prof. J. C. Philip, and its members are as follows: Dr. W. A. S. Calder, Dr. W. Cullen, Mr. J. Davidson-Pratt, Dr. L. H. Lampitt, Sir Gilbert Morgan, Sir Robert Pickard, Dr. R. E. Slade.

As a result of the Committee's recommendation the leading chemical societies and related bodies had invited their members to volunteer for the Register. The Association of British Chemical Manufacturers had also, with the Committee's approval, approached its employer members asking them to encourage qualified members of their staffs who are not in membership of one or other of the co-operating technical bodies to apply for inclusion in the Register. It is, of course, still open for any individuals not members of the associations mentioned, who are qualified by training and/or experience, to volunteer by communicating directly with the Central Register Branch, National Service Department, Ministry of Labour, Montagu House, Whitehall, S.W.1.

The Industrial Chemistry Committee also has been studying in greater detail the cards filed in the various sub-sections of the industrial chemistry classification, and, apart from certain necessary adjustments as between this section and the section for research chemists, it is proposed to consider the steps which should be taken to supplement those sub-sections where the present number appears to be inadequate in relation to war-time demands.

The number of volunteers enrolled in this section was 4,985, at the end of July. While this result is regarded as moderately satisfactory, it is understood that there has been reluctance on the part of some employers to allow qualified members of their staff to enrol. This may be due to a misconception of the use to which the Register will be put in war-time. The selection of persons for submission to posts will be made by experts in the particular field, working within the general scheme of priorities laid down by the Government.

Further, before volunteers already in employment are submitted for alternative posts the observations of their existing employers will be carefully considered by expert committees appointed for the purpose. It is therefore hoped that in the national interest employers will encourage their qualified staffs to enrol on the Register, so that it may be equal to the calls made upon it. It is to be remembered also that the Register will be available for the use of employers as well as of Government Departments, and that in certain circumstances they may find it of great use for securing replacements of staff.

Reference has been made above to two only of the several sections of the Central Register of Specialists, namely, scientific research and industrial chemistry, the detailed working of which will be of special interest to readers of NATURE. The complete register covers every aspect of professional and intellectual activity of a modern civilized State. The whole conception is an eminently scientific undertaking, approached in a scientific manner with full consideration of all the pitfalls of which the experience of the war of 1914–18 made the community aware. However much we may deplore the circumstances through which the Central Register has arisen, it should be welcomed as an invaluable record of the scientific and learned life of Great Britain which will prove of inestimable service now and in happier times when reconstruction begins.

STANDARDS OF PHYSICAL MEASUREMENT

National Physical Laboratory Collected Researches
Vol. 24: Standards. Pp. iii + 450 + 19 plates. (London: H.M. Stationery Office, 1938.) 22s. 6d. net.

STANDARDS provide the foundation for the intelligent co-ordination of all physical measurements. The refinement with which this co-ordination may be carried out rests fundamentally upon the precision with which the values of these standards are known and the extent to which they are utilized by research men in expressing their experimental results. The present volume of ten papers on standards shows the fidelity with which the National Physical Laboratory is carrying out its functions in establishing standards of measurement worthy of the name.

Electrical Measurements. The 'International' system of electrical units was adopted by the International Electrical Congress held in Chicago in 1893. Great difficulty was later encountered in establishing precise standards on the basis of the mercury ohm and the silver voltameter. The situation was temporarily met in 1910 through a joint decision of the standardizing laboratories of the leading nations to adopt consistent values for their standard resistances and standard cells, based on an intercomparison of their national standards. But some of these national standards began to drift, and the temporary uniformity was lost. Furthermore, it was soon recognized that the 'International System' departed by several parts in 10,000 from the absolute system of electrical units.

In 1929, the International Committee on Weights and Measures requested the various national laboratories to undertake the establishment of the electrical units in absolute measure. Two of the papers in the volume under review represent the contribution of the National Physical Laboratory to this undertaking.

The first of these deals with Vigoureux's absolute determination of the ampere. The current balance used in earlier work at the National Physical Laboratory was modified for this purpose, the most important change being the construction of new coils. Numerous measurements led to the conclusion that the unit of current at the National Physical Laboratory as realized by means of resistance coils and standard cells is 14 ± 3 parts in 100,000 less than the absolute ampere.

The accuracy of this result is believed by Vigoureux to be affected mainly by (1) systematic errors, (2) want of exact knowledge of the linear dimensions of the coils and (3) uncertainty in the absolute value of the local acceleration of gravity, which was derived from the Potsdam measurements. It may be stated parenthetically that recent absolute measurements of g both at the National Physical Laboratory and at the National Bureau of Standards give values slightly less than the classical Potsdam determinations.

A second paper by Vigoureux deals with the absolute determination of the ohm by the method of Lorenz. The Lorenz machine erected at the National Physical Laboratory in 1912 was used in this work, but new apparatus was constructed for adjusting the four inductance coils coaxially with the shaft and for determining the distance between the coils. The dimensions of the coils were also re-measured. The results showed that the National Physical Laboratory 'International' unit of resistance exceeds the absolute ohm by 50 ± 3 parts in 100,000.

Two other electrical papers appearing in the volume afford significant examples of international co-operation. "The Capacitance and Power Factor of a Mica Capacitor" is a joint contribution of Curtis and Sparks of the National Bureau of Standards and Hartshorn and Astbury of the National Physical Laboratory. Two radically different methods were used. At the National Bureau of Standards the mica capacitor was compared by alternating current with an air capacitor, the capacitance of which can be evaluated in terms of resistance and time. At the National Physical Laboratory the comparison was made by means of alternating current with a mutual inductance, which can be evaluated from its dimensions. The two methods gave results in agreement within 1 or 2 parts in 10,000, which is about the accuracy of the measurements.

The "International Determination of the E.M.F. of the Normal Weston Cell in International Volts" by Vigoureux likewise gives the results of a joint investigation by the Physikalisch-Technischen Reichsanstalt, National Physical Laboratory and National Bureau of Standards. The final value was 1 0183 volts at 20° C., which confirms the recommendations of the International Technical Committee in 1910.

A paper by Davis, Bowdler and Standring deals with the difficult problem of measuring peak voltages. Two methods were employed: (1) The voltage on the low-voltage arm of a condenser-divider was rectified. (2) The current through a condenser connected across the voltage to be measured was rectified and the mean current used as a measure of the peak voltage. Agreement to 2 parts in 1,000 was obtained.

The Thermometric Scale. A temperature between 0° C. and 100° C. on the 'International Temperature Scale' is evaluated by means of the platinum resistance thermometer. In his paper on this subject, Hall compares the platinum scale with the earlier N.P.L. scale maintained by mercury in verre dur thermometers. He found differences as large as 0·02° C. between individual mercury thermometers, but for selected thermometers the change to the platinum scale did not change the N.P.L. scale more than 0·002° between 0° C. and 50° or more than 0·005° between 50° C. and 100° C.

Another example of international team-work is to be found in the paper "International Comparison of Temperature Scales between 660° C. and 1063° C." by Roeser of the N.B.S., Schofield of the N.P.L. and Moser of the P.T.R. After exchanging thermocouples and samples of silver, the temperature scales of the three laboratories were brought into agreement within 0·1° C. at all points in the range covered.

Metrology. Stott's investigation of pivots and jewels as used in instruments and meters is an outstanding contribution to this subject. It covers the production of accurately shaped pivots, deformation under loading, friction, wear and lubrication. The paper should be studied by everyone who uses pivots and jewels in fine instrument design.

Under the title "Determinations of the Fundamental Standard of Length in Terms of Wave-Lengths of Light", Sears and Barrell present the results of their precise measurements in this field. An accompanying paper describes the apparatus. Their determination of the metre in wave-lengths of the red radiation of cadmium is in good agreement with the results of other observers. In fact the mean of all these determinations is practically identical with the value obtained by Benoît, Fabry and Perot, upon which all modern spectroscopic wave-length tables are based. The authors wisely urge that this relationship be preserved in any future definition of the unit of length in terms of wave-lengths of light.

Sears and Barrell also carried out for the first time a direct determination of the length of the Imperial yard in terms of wave-lengths of the red radiation of cadmium, from which the ratio of the yard to the metre may be derived. They direct attention to the advantage of re-defining the yard in terms of light-waves so chosen in number that 1 inch = 25·4 mm. or 1 yard = 0·9144 metre, exactly. This simple factor represents closely the mean between the present yard of Great Britain and that of the United States. Its official adoption would involve a change of not more than two parts in a million by either nation. It would not disturb industry in the slightest, because as a matter of fact this ratio has been in industrial use in both countries for many years. The National Bureau of Standards is in hearty accord with this proposal.

LYMAN J. BRIGGS.

BUILDING RECOMMENDATIONS

Principles of Modern Building
Vol. 1: Walls, Partitions and Chimneys (Department of Scientific and Industrial Research). By R. Fitzmaurice. Pp. 400+20 plates. (London: H.M. Stationery Office, 1938.) 10*s.* 6*d.* net.

ONE of the principal functions of the staff engaged at the Building Research Station, Garston, is to provide answers to the numerous inquiries received from all branches of the industry. These have led to the examination of building practice from every possible point of view, and this volume, compiled by the member of the staff responsible for dealing with these inquiries, contains information which has been collated from an experience unique in its extent and in its authoritativeness. This volume deals only with walls, partitions and chimneys, and is the first of a series the preparation of which has been undertaken at the joint request of the Royal Institute of British Architects and the Chartered Surveyors' Institution. It represents also the first fruits of a suggestion contained in the interim report of the Ministry of Health Committee on the Construction of Flats for the Working Classes.

Here is no mere recapitulation of established method and practice. The aim has been to formulate a statement of the functions of a building, as these are now understood, and the elements in its composition, and thus to guide the practical man in adapting his work to meet present-day requirements. Such problems as those of obviating dampness in walls, of avoiding smoky chimneys, and of providing insulation against the penetration of sound are representative of the useful points discussed. Of special value are the sections which deal with load-bearing walls both of the solid and of the cavity types and those in which new or recently introduced materials are discussed. An outstanding feature of the book is the concise, clear manner in which practical recommendations are given.

The necessity for such an authoritative series of volumes of reference can be understood when it is remembered that, until recently, building practice was subject only to very gradual changes. The rapid developments of modern times have led to the introduction of a multitude of innovations, some of which can be described as ill-advised. In showing the designs and methods which have been closely scrutinized and finally approved at the Building Research Station, this volume can be seen to be an invaluable contribution to the formulation of a code of good practice. It has been attractively prepared, is profusely illustrated with photographs, drawings and graphs, and is supplemented by lists of references and of appropriate British Standard Specifications.

THE CALIFORNIAN DESERTS

(1) The Californian Deserts:
a Visitor's Handbook. By Edmund C. Jaeger; with Chapters by S. Stillman Berry and Malcolm J. Rogers. Revised edition. Pp. x+209. (Stanford University, Calif.: Stanford University Press; London: Oxford University Press, 1938.) 9s. net.

(2) Deserts
By Dr. Gayle Pickwell. (Whittlesey House Publication.) Pp. xiv+174 (64 plates). (New York and London: McGraw-Hill Book Co., Inc., 1939.) 15s.

(1) HERE is a model guide-book, for its presentation is artistic, its facts correct and well chosen and the deductions therefrom modern. A desert is a place of high summer temperatures with steady, drying winds and a rainfall not exceeding five inches; these are usually accompanied by a high, diurnal temperature range, here about 40° F. There are complications, for the rain-carrying winds rise in the Gulf of California, cross mountains and descend in occasional bursts on a dissected, mountainous land, extending from the Colorado River for two hundred miles along the inland half of California. The possible evaporation appears to be 80–100 inches, so that the intensity of the aridity is considerable. These conditions have only been reached since the end of the Pleistocene, and there would appear to have been several periods of wetness. To the south the fertile belt of the Colorado separates the similar desert of Arizona and Sonora (Mexico), and there have always been in both deserts lake and other areas of permanent water such as the famous 'Death's Head Valley' and the 'Salton Sea' in California.

Comparisons with Old World deserts are impossible, for here are more than seven hundred species of plants. Many are supposedly desert-adapted, but caution is advised, since marsh and bog plants, owing to an absence of nitrogen, may show similar changes Some of the peculiar races are doubtless evolutions of northern plants, but there has probably been extensive immigration from the high, more ancient desert-lands of Sonora.

Insects are a function of plant-growth, so that there must be several thousand species, mostly living in inconspicuous habitats; the most visible are treated of in an interesting chapter. Snails and higher animals are well considered, the whole leading to a naturalist's account of the mammals, which are represented by thirty-six genera, including beavers which have given up the dam-making habit. The preservation of the bighorn sheep, of which about 600 are left, is immediately important, since experience has shown that the area occupied by a wild race of sheep which has been destroyed cannot be readily repeopled by sheep from other areas.

The Californian deserts are laboratories, conveniently situated for study; the experimental research is that of Nature, the lines those of past times, and hence peculiarly suited to the study of the changes which are due to natural evolution.

(2) Dr. Pickwell in his turn provides 64 full-plate photographic illustrations of these same deserts. His text for the most part is explanatory of these, to which is often added original observations on the biology of some of the plants and animals pictured. Unfortunately, many of the reproductions appear rather black-and-white so that frequently where detail is needed in the plants, it cannot be found. My own experience in similar landscape photography in the tropics leads me to suggest that for plants and forests a side light with consequent low-toned shadows is desirable, my practice being to close the camera for the six hours of midday. A concluding chapter summarizes the desert features and problems, subjects upon which experimental researches are urgently required, especially in respect to the water requirements of animals.

J. S. GARDINER.

INSTRUMENTS IN SCIENCE AND INDUSTRY*

By Robert S. Whipple

I FEEL that it is a great honour to be chosen as president of Section A of the British Association, particularly because on looking through the names of my distinguished predecessors I find that I am the first professional maker of scientific instruments to occupy this chair. My immediate predecessor, Dr. C. G. Darwin, who now occupies the important position of director of the National Physical Laboratory, gave us at Cambridge a brilliant dissertation on the use of mathematics in solving physical problems, and the need of the mathematical outlook when facing a series of facts requiring solution. He would, I am sure, be one of the first to insist that the mathematician requires physical facts to enable him to develop a physical theory, and that the probable soundness of the theory will depend largely upon the accuracy of the data discussed. In the majority of cases this accuracy depends on the qualities of the apparatus employed in the observations, assuming that the observer is fully qualified and capable of obtaining the best results from it. I believe that all such observers now demand far more from their apparatus than was formerly possible, but few realize the amount of thought and labour involved in raising the accuracy obtainable from one to one-tenth of one per cent.

The help that instruments have given to the advancement of science is a fascinating theme, and at the same time a wide one. Among the earliest and most striking examples we find that Kepler was able to state his laws of planetary motion as a result of the observations made with Tycho Brahe's carefully constructed instruments. Tycho (1546–1601) first introduced (though he did not discover) the method of transversal division of the arc, which is now familiar to us as the basis of the diagonal scale. It was he who first pointed out the importance of symmetry in an instrument. The ingenious naked-eye sights developed by him were a remarkable improvement on the simple sights previously used. According to Dreyer, his determinations of the right ascensions and declinations of his nine standard stars show a probable error of less than thirty seconds of arc—an almost incredible achievement.

I propose to consider a few well-known instruments and to use them as examples to indicate how the development of a particular subject has grown largely with the perfection of the instruments used to investigate it. It is in every way a reciprocal process. By means of an instrument certain evidence is obtained; this evidence does not go far enough and the instrument must be improved to enable further facts to be found. If, for example, the biologist requires to examine small bodies beyond the range of his microscope, he appeals to the physicist to help him, and the appeal is not in vain. Most probably, as a result of the work on his colleague's problem, the physicist develops a technique which will be of service to him or to a fellow-physicist.

The Microscope

The first example I shall take is the microscope, an instrument which is used in every observational science and, in some form or another, in nearly every industry. The early story of the microscope has been often told, and yet it may be of interest to recall the most important stages in its development. The first instruments consisted of single lenses, actually small globules of glass, which, when the surfaces were suitably ground, yielded in the hands of skilled observers surprisingly good results. The outstanding example is the Dutch naturalist Leeuwenhoek, who during the period 1674–1723, using a microscope of this type, discovered the protozoa and bacteria, and made many other biological observations of supreme importance.

Hooke, who was Leeuwenhoek's correspondent, was working in microscopical problems at the same time, and in the "Micrographia" (1665) described his own microscope—the first compound microscope. The optical system of this instrument consisted of a converging lens, called the object-glass, the field lens, and a third lens, the eye lens. Although it has been stated frequently that Hooke first introduced the field lens to enlarge the field of view, there is little doubt that this invention was due to Monconys, who published a short description of a compound microscope made to his design in 1660. This scarcely detracts from the credit due to Hooke, whose publication became so generally known, and whose optical system was universally adopted and remained practically unchanged for more than a hundred years.

Hevelius, in 1673, described in his "Machine Coelestis" a screw-focusing adjustment that he had fitted to an instrument of the Hooke type which was the forerunner of the modern mechanism adopted (or invented independently) by John Marshall (1663–1725), one of the great opticians at the close of the seventeenth century. Marshall should be remembered by the fact that he was the first to introduce the method of grinding a number of lenses simultaneously, by cementing a number of pieces of glass on to the surface of a large convex spherical block, and working them with a concave spherical tool. This is still the method employed for polishing lenses in quantity. In the modern spectacle lens factory as many as a hundred and fifty are sometimes polished in one block.

---

* From the presidential address to Section A (Mathematical and Physical Sciences) of the British Association delivered on August 31.

Although many variations in the design and mechanical construction of the microscope were made during the eighteenth century and the early years of the nineteenth, yet there is no invention of fundamental importance to record until the construction of the achromatic objective. This was first successfully completed by the French optician Chevalier about 1825, and in England by Tulley working about the same time to the designs of Joseph J. Lister, nearly sixty years after the construction of a successful achromatic telescope objective.

Abbe carried the corrections of the aberrations to a far higher degree of perfection, notably by using glasses of new types which at his suggestion had been worked out by Schott, to produce, about 1886, the so-called apochromatic objective in which the colour correction was greatly improved.

It is difficult to see how the resolving power of the microscope is to be further increased using light from the visible region of the spectrum. The biologist, and particularly the medical man, is anxious to study organisms the structure of which is too fine to be resolved by any object glass when using ordinary white light, the alternative to which is the employment of rays of shorter wavelength, namely, the ultra-violet. Glass lenses are opaque to these short wave-lengths, and therefore lenses made of fused quartz must be used. J. E. Barnard, who has developed a very successful technique in connexion with ultra-violet microscopy, has shown that it is possible to study and photograph living bacteria, which are normally transparent to light from the visible region of the spectrum, without staining and therefore killing them. The use of such short wave-lengths has necessitated the construction of extremely rigid mountings in the microscope body and complete absence of play in the moving parts of the instrument. As showing the perfection of the technique obtained with ultra-violet microscopy, it may be mentioned that it is possible to take a series of photographs of an object in successive parallel planes separated by distances of the order of 0·0002 mm.

The use of short-wave radiations has proved so successful in the case of the ultra-violet microscope that a technique has been developed which offers great possibilities for the use of still shorter radiations. As is well known, a beam of cathode rays can be brought to a focus by passing the beam through a magnetic or electrostatic field, in a manner very similar to that in which light is brought to a focus by a convex lens. In the same way, an electron image of a surface may be formed owing to the fact that the electrons will be scattered by an amount depending on the density (or mass concentration) of the surface on which they impinge. By forming the image on a fluorescent screen it can be rendered visible, or if projected on to a sensitized plate, photographically recorded.

In an instrument designed by Von Borries and Ruska, an electron stream is passed through two specially designed electromagnets (or magnetic lenses), mounted one above the other, which act as equivalents to the objective and eye-piece of an optical microscope. If an object is placed between the poles of the lower magnet, some of the electrons will be scattered by the material of the object and others will be diverted by the magnetic flux so as to form an image of the object in a plane below the magnet. That an image can be formed in this way depends upon the fact that the scattering is proportional to the mass concentration at different parts of the object. The scattering will be greater from the thicker parts than from the thinner ones, and thus the dark parts of the image will correspond to the thick parts of the object, and *vice versa*. Magnifications of about twenty times those obtained with the optical microscope can be obtained. Excellent photographs have been taken of bacteria and bacilli at magnifications of 10,000 and 20,000 diameters.

Sorby, in 1864, was the first to investigate the structure of metals and alloys by the microscope, and although it was a considerable time before his work was appreciated, there is now no metallurgical laboratory worthy of the name that does not possess a microscope by means of which the molecular structure of an alloy can be examined and photographically recorded.

THE TELESCOPE

Although the discovery of the telescope antedated that of the microscope, in its service to mankind it ranks as second to it. The credit of the invention of the telescope must go to a Dutchman, Lipperahey; yet it was Galileo who first produced an instrument worthy of the name. He ground and polished his own lenses, and in 1610, with a telescope magnifying thirty-three diameters, discovered the satellites of Jupiter. Amongst his many astronomical observations he discovered the phases of Venus, and estimated the height of the lunar mountains from the length of their shadows.

Newton pointed out that the focal length of the refracting telescope could not be reduced owing to the refrangibility of light of different colours, and that it was not possible to focus for all the colours simultaneously and thus obtain a sharp image. He measured and calculated the distance between the foci of the red and violet and showed that it was about 1-50th the diameter of the lens. It was to overcome this difficulty that the glasses were made small and of long focal length. It is almost unbelievable that James Bradley, in 1722, measured the diameter of Venus with a telescope having a focal length of 212 ft., the supporting mast being about 45 ft. long.

In 1663, James Gregory suggested the construction of a reflecting telescope, and in 1668 Newton constructed the first practical instrument, having made his own alloy for the mirror and having devised methods for grinding and polishing it. A sentence in his "Optiks" (Bk. I, Pt. 1, Prop. VI, p. 75) shows how serious the position had become: "Seeing therefore the improvement of Telescopes of given length by Refractions is desperate; I contrived heretofore a Perspective by reflexion, using instead of an Object Glass a concave Metal."

The manufacture of satisfactory reflectors was very difficult, and it was not until an instrument maker, James Short of Edinburgh, about 1730, produced instruments with parabolic figuring, that the reflector came into general use. His instruments, even now, may be regarded as examples of first-class workmanship.

Sir William Herschel began making specula in 1774 and constructed a large number of reflecting telescopes, the most famous being his instrument at Slough of 4 ft. aperture and 40 ft. focal length; this was completed in 1789. Unfortunately, the weight (25 cwt.) of the large speculum rendered it liable to distortion, and it is of interest to note that all Herschel's discoveries were made with smaller instruments. More than fifty years later a reflector of 6 ft. aperture and 54 ft. focal length was erected by Lord Rosse at Parsonstown. All these instruments were fitted with metal mirrors which had an unfortunate tendency to tarnish, and re-polishing was apt to spoil the figuring of the mirror. In the modern instrument the metal mirror is replaced by glass which can be re-silvered at intervals. During the last few years aluminium has taken the place of silver as the reflecting surface, the aluminium being deposited on the glass surface under vacuum. The aluminium film does not tarnish, is more robust than silver and has a higher coefficient of reflection for short wave-lengths, and is thus more efficient photographically.

Owing to the increasing demand for telescopes of higher magnification, and of increased light-gathering power, the size of the mirrors used in the modern instruments is steadily increasing. The Mount Wilson Observatory has a telescope with a mirror 100 in. in diameter, and it is a matter of common knowledge that magnificent photographs of nebulæ, etc., have been obtained with it. At the present time an instrument having a mirror 200 in. in diameter is being constructed for the Mount Palomar Observatory. The manufacture of the borosilicate glass (pyrex) block for this mirror, which weighs twenty tons, has been a feat of considerable skill, and if it is successfully ground and polished, as appears likely, it will be a great engineering triumph. We have become so accustomed to success in mounting and operating these large telescopes, that we are apt to forget that this is the heaviest and certainly the most impressive side of instrument construction work.

For the large telescope the reflector has established itself as the most satisfactory instrument, whereas for the smaller telescope, and for the everyday purposes of life, the refractor is still the more efficient. In 1733, Chester Moor Hall found that by combining lenses made from glasses having different refractive indexes he was able to correct for the unequal refrangibility of light of different wave-lengths, and succeeded in making lenses which produced images free from colour. The same discovery was made independently by John Dolland, who, in 1758, produced an achromatic telescope in which the object glass consisted of a convex lens of crown glass combined with a concave lens of flint glass. The invention of the achromatic lens must be considered as one of the milestones in the development of scientific instruments.

THE SPECTROSCOPE

Perhaps there is no instrument which in recent times has aided pure science so much, and is now beginning to help industry, as the spectroscope. Fraunhofer constructed the first spectroscope in 1817, and made the first measurements of the lines of the solar spectrum. He was also the first to observe the spectrum of the electric spark. In 1842, Becquerel and Draper independently photographed the solar spectrum on daguerreotype plates, thus laying the foundation for the modern science of spectroscopy.

In 1859, Kirchhoff showed that the luminous vapour of a metal has the property of absorbing the same kind of light as it emits at the same temperature. Kirchhoff recognized the fundamental importance of his discovery, entitling it "spectrum analysis"; but it is largely due to Hartley (1882) and later to Twyman, who designed simple and efficient instruments, that spectroscopic analysis has become a quantitative method of chemical analysis. The spectrograph is now one of the most important tools in the metallurgical and chemical laboratory. In the manufacture of steel it is proving an invaluable check on the quality of the materials, the spectrogram obtained from the sample under test being compared with that taken from a standard. The speed of analysis may be judged from the statement that it is possible for one man to analyse twelve samples of nickel-chromium-molybdenum steel spectrochemically for the elements silicon, manganese, nickel, chromium, molybdenum, vanadium, aluminium and copper in less than one day. The spectroscope has also become a tool in common use in the steel warehouse, the storekeeper being able by its means to detect any mixing of the batches of steels.

In the laboratories of the works producing non-ferrous materials the spectroscope is proving equally efficient. For example, the failure of lead pipes from causes other than frost has been considerable, and has been traced to impurities in the lead. A spectroscopic examination of the pipe that has failed shows in a few minutes the undesirable impurities present, and, if the examination is carried further, the quantities of those impurities.

Our knowledge of the constitution of the celestial bodies is almost entirely due to the spectroscope. By its means it has been possible to discover what elements are present in the vapour surrounding them. This was strikingly shown by the discovery by Lockyer, in 1868, of an unknown gas (helium) in the bright-line spectrum of the sun's atmosphere, which was identified by Ramsay twenty-seven years later in the terrestrial atmosphere. The photographing of the sun's disk in a limited band of wave-lengths has led to the development of a special form of recording spectroscope, the photo-spectro-heliograph. In this instrument the slit of a spectroscope is slowly traversed across the sun's image, the selected radiation falling upon a photographic plate. Thus a picture of the sun is built up from a series of photographs taken in the selected wave-lengths. For example, if the wave-length selected is one of calcium, a picture of the disk is obtained showing the distribution of calcium over the sun's surface. The major part of the knowledge obtained about the double stars and also the determination of the velocity of stars in the line of sight has been obtained from spectroscopic observations. The theory of the expanding universe may be said to rest on spectroscopic observations.

SURVEYING INSTRUMENTS

The distinction between the telescope suitably mounted to survey the heavens and that used to measure distances upon the earth's surface is a faint one. The transit instrument is in general only a larger form of theodolite. The early surveyors (and here we may go back to early Egyptian times) made plans by means of rods and plummets; but it was not until the invention of the astrolabe and the use of a divided circle fitted with sights that accurate surveying was attempted. The first mention of the word 'theodolite' occurs in a book "Pantometria" (1571) by an Englishman, Thomas Digges. (It is a matter of interest that Digges has some claim to be called the inventor of the telescope). The early the odolites, like the astronomical instruments, were fitted with pinhole sights: in the case of the latter instruments, an important controversy arose between Hooke and Hevelius (1679) concerning the relative advantages of telescopic and open sights. Although Hevelius was not convinced, the telescopic sight was almost invariably used after that date. Mention should be made that William Gascoigne invented the filar micrometer and fitted it to a telescope in 1640: this invention greatly increased the accuracy of instruments to which it was attached. Bradley's observation in 1722 shows that he used a form of filar micrometer with considerable success.

As the demands of the astronomer (and later of the surveyor) increased, so the need for improved divided circles became more urgent. The accurate dividing of circles has always been one of the more difficult tasks of the instrument maker, and it is almost entirely due to the English manufacturer that the art of dividing has reached its present high position.

In 1766 Jesse Ramsden made his first circular dividing engine, but as it was not sufficiently accurate for dividing the scales of nautical instruments, he completed a second machine nine years later. It was with this machine that he divided the circles of the 3-ft. theodolites used in the principal triangulation of Great Britain and Ireland, 1792–1862. They were divided to 10 minutes and read to one second of arc by three micrometer microscopes.

In 1826, William Simms invented the self-acting mechanism by means of which the dividing machine became completely automatic, thus saving an immense amount of time, and reducing the risk of error in the dividing of a circle. A similar but larger machine, built by G. W. Watts in 1905, is capable of dividing a circle 4 ft. 6 in. in diameter to 30 seconds of arc with an error not exceeding ± 1 second.

Linear scales are automatically divided by somewhat similar machines in which are fitted a temperature compensation device for variation in the temperature of the machine and a compensation device for correcting for any variations in the pitch of the master screw. In this connexion the scientific man and the instrument maker are alike indebted to the late Dr. C. Guillaume for the invention of 'invar', a nickel-steel alloy having a remarkably small temperature coefficient of expansion, and hence an almost ideal material from which to manufacture standard scale and measuring tapes. In the case of linear scales, the position of the lines in a good metre scale can be guaranteed to an accuracy of 0·002 mm

THE THERMIONIC VALVE

An address of this nature would be incomplete if no mention were made of the thermionic valve. Its advent has led not only to the birth of a wide range of new instruments otherwise impracticable, but also to the simplification of many measuring techniques. The thermionic voltmeter was one of the first, if not the first, measuring instrument employing directly a valve, and uses to the full its most valuable characteristics as a measuring device. These characteristics may be briefly summed up as rectification, amplification, rapidity of response, and high impedance. Although these are the prime considerations, others, such as high overload capacity, are advantageous. The rectifying action combined with amplification enables alternating currents and voltages as small as 10^{-4} ampere and 10^{-4} volt to be measured, using a robust moving-coil instrument as a direct reading indicator. The low electrical inertia and high input impedance have, when using suitable diode valves, enabled voltages and frequencies up to 100 megacycles to be measured with reasonable accuracy by robust commercial instruments.

MANUFACTURE OF SCIENTIFIC INSTRUMENTS

Looking back over forty years' experience in the use of scientific instruments, many of those years being spent in their manufacture and development, I am much impressed with the steadily growing demands for higher accuracy. The development of the high-speed steam engine, and later the motor-car, brought about an insistent demand for accurate tools and gauges. This in its turn necessitated better design in the tools and more accurate measuring instruments. The manufacture of interchangeable components in large quantities has still further increased the demand for accuracy. The introduction of the new alloy steels with the special technique required in their heat treatment created a demand for precision thermometry.

The attitude of the manufacturer towards the scientific instrument has completely altered. He was once sceptical as to its usefulness; he is rarely so nowadays. In the majority of large works the general control over the instruments is now in the hands of a technically trained man, and that in itself relieves the instrument maker of much anxiety. Another fact that impresses one is the great difference between the methods of manufacture during the same period. Forty or fifty years ago, instruments were made in small batches, often by individual workmen. In London they were frequently made for some well-known firm by small chamber men who put the name of that firm upon them. As a result of this procedure, the so-called manufacturer very often had not an adequate knowledge of his products: this practice has almost entirely disappeared, to the benefit of customer and maker.

The increased demand for instruments has led to manufacture in the modern sense of the word. An instrument is carefully designed in the drawing office in consultation with the technical expert. The methods by which the instrument is to be made are considered. If the quantities are large, and if a preliminary model has been approved, then the possibility of the use of die castings, hot pressings or plastic mouldings must be considered, and the importance of interchangeability of components emphasized.

In preparing the design of an instrument it must never be forgotten that a good design helps production. It always pays to spend time in the drawing office rather than in the workshop. The application of geometric design, the early exponents of which were Maxwell and Horace Darwin, often reduces the cost of manufacture and makes a better instrument. I think that the experimentalist, in making up his own instrument, should consider whether he can obtain the same result by a simply designed geometric piece of apparatus, rather than the more elaborate design to which he may be attracted.

The demand for instruments is ever growing. As new problems arise, both in science and in industry, the requirements become more stringent. The instrument maker constantly receives incentives to progress from the scientific worker, to whom he owes not only suggestions but also many of his new materials. It is, I suppose, a truism that if knowledge is to progress it is essential that theory and practice advance together. Nowhere is this more true than in the development of scientific instruments.

THE ASSESSMENT OF PHYSICAL FITNESS*

BY PROF. DAVID BURNS

TESTS which have been used to assess fitness fall into three classes: (1) somatometric; (2) physiological; (3) psychological.

SOMATOMETRIC TESTS

The search for a relationship between the configuration of the body and physical fitness has been pursued since the time of Hippocrates. Such a relationship is elusive, and because of the complexity of body build and the scarcity of strictly comparable measurements, most of the findings lack validity.

It was natural, at first, to consider stature as an index of robustness. The tall man with a long reach was better able to hold his own in hand-to-hand fighting. Even to-day, height is taken into account in selecting recruits for the services and the police. The tall applicant, too, has generally a better chance of getting engaged in commerce and industry than his shorter competitor. Length, especially length of leg, is not merely an indication of genetic constitution but also of a late incidence of maturity. Chest girth in relation to size of body, at first sight, appears to have at least a probable relationship to fitness, but Gould (1864), who carried out a thorough statistical survey of the manhood of the American nation during the progress of the Civil War, had grave doubts as to the validity of chest measurements for this purpose. Hutchinson showed clearly that the circumference of the chest is no measure of vital capacity, endurance or even of muscular strength, nor is there any evidence that it bears any relationship to the state of general health.

Criteria of Fitness. Since the introduction by McLaren of systematic somatometric measurements as part of the routine of physical education, there has arisen a host of indexes, of which perhaps the best known are Von Pirquet's Pelidisi and Franzen's A.C.H. indexes.

In general, chests may be divided into three types: the wine-glass—wide shoulders and narrow hips; the test-tube—both measurements small; and the barrel with broad shoulders and wide hips. Persons of the test-tube type are often abdominal breathers, that is, they obtain their tidal air by contracting the diaphragm and displacing the viscera into a relaxed abdominal wall. Experiment shows that they have a larger effective vital capacity than the others and are generally more amenable to training. On the other hand, all three types are normal and are equally fitted, so far as bodily relations go, for the battle of life. One cannot mark down any type as fundamentally healthier than the others. The test-tube type is more prone to tuberculosis but less prone to rheumatism, diabetes and arterio-sclerosis than the barrel.

None of these indexes is valid as a measure of fitness, even when due allowance is made for race, type of body build, sex or occupation.

PHYSIOLOGICAL TESTS

Fitness is functional. The body must be tested at work. The measurement of vital capacity is generally classed as physiological although it is not strictly functional. This measurement, a common routine practice, has no real significance. The amount of air that a person can contain in his lungs is a measure of chest capacity and of the tone of the respiratory musculature, but the person with an extra large vital capacity has no advantage over one who has quite a small capacity provided that he has sufficient.

There is a prevalent error that so-called deep-breathing exercises where the shoulders are forced back and the chest brought forwards and upwards increase vital capacity. Actually, by fixing the pectoral muscles and stretching the abdominal wall, these procedures prevent full inspiration and expiration and increase the volume of air left in the lungs (residual air). Chest breathers have about the same vital capacity, whether taken at ease or on the stretch, while 'deep breathing' may reduce the vital capacity of abdominal breathers by about 30 per cent. The value of deep-breathing exercise lies in its effect on the filling of the heart and so on the maintenance of cardiac efficiency.

One is on surer ground when using the various breath-holding tests either *per se* or against pressure. The former is a measure of the alkali reserve of the blood and of the determination of the subject not to give in. The 40-mm. test brings out both these qualities and, in addition, is a severe test of muscular strength and control.

Bainbridge and Dawson quote the results of experiments which show clearly that fit and/or skilled men carry out physical work with but a slight increase in lactic acid, while the unfit, under the same conditions, have a higher blood-lactic acid content. That is, the reserve of alkali in the blood of the fit is large enough to cope with all or most of the acid released as a result of muscular exercise. Recruits have on the average 5 per cent less available base than the soldiers. Dawson states that three months' systematic physical education can raise the amount of available base by about 10 per cent.

---

* From the presidential address to Section I (Physiology) of the British Association, Dundee.

Similar 'fitnesses' associated with other groups of muscles can be tested by various dynamometers. Martin introduced a new procedure into this type of test. Instead of measuring the strength of a subject's active pull on a dynamometer, he applied the pulling force to groups of muscles and recorded the force necessary to break down the subject's active resistance to the movement of the muscle-group under test. The summation of a series of selected groups of muscles thus gives an indication of the total muscular strength of that individual as well as of his determination to resist. It gives no measure of his skill or of his economy of movement. It may be asked: Is muscular strength plus determination an adequate measure of general fitness?

Limiting Factor of Efficiency. It is well known that the limiting factor, the factor which determines whether muscular strength can be exerted to its full extent, the factor which overrides the will to do, is vaso-cardiac efficiency. Goodall recognized this when he published his efficiency tests. If, after a measured amount of exercise, the pulse rate and blood pressure come back to normal in a specified time, depending on the severity of the exertion, then the subject of the test is fit.

With a healthy heart, cardiac efficiency ultimately depends on the venous filling. A pump without a well may be a thing of beauty, the last word in mechanical efficiency, but its usefulness is non-existent. About 85 per cent of the total volume of the blood is in the capillaries and veins under normal conditions. Under these conditions, all capillaries are not patent at any one time. The splanchnic viscera, and particularly the liver and the spleen with their rich venous supply, are capable of retaining much larger quantities of blood than they do. If, for any reason, more capillaries open up at the same time and the splanchnic reservoir becomes filled with blood, the amount freely circulating, the amount necessary to fill the receiving chambers of the heart, becomes inadequate. The controlling factor in the distribution of blood, in maintaining an effective circulation, lies mainly in the tone of muscle—cardiac, visceral and, last but by no means least, ordinary skeletal muscle.

The venous return is also aided by the rhythmic alterations of intra-thoracic pressure with the phases of the respiratory act. It is, however, only in abdominal breathing that the respiratory act aids the return of blood to the heart. These alternating pushes and pulls, produced by muscular action dependent on the tone of the diaphragm and muscles of the abdominal wall, have a minor effect on venous return in comparison with the constant tonic push of muscle in general. During exercise, more capillaries in muscle become patent and, if muscle is in good tone, more blood is put under tissue pressure. On the other hand, if tone is at a low level, blood filling the capillaries is not pressed out, congestion appears and the heart fails through lack of blood. The fit person whose heart is able so to increase its output per unit of time that adequate blood is supplied to active tissues to meet their increased needs, must have a higher value of muscle tone than the unfit. Experiment shows that healthy young men have a tone in their relaxed left biceps muscle which is capable of withstanding a pressure of 60–90 mm. of water, while patients in bed have an intra-muscular pressure of about 50 mm. of water.

Intra-muscular pressure is markedly increased when muscle contracts, so that, as the fibres in muscle shorten intermittently during exercise, the blood is expelled from the venules in the muscles intermittently. This pulsation plays an important part in maintaining the tone of the vessel walls. The hæmostasis produced by immobile standing, shown by swelling of the legs in unfit persons, may be prevented by almost imperceptible voluntary twitches of the calf muscles or even by movements of the toes. Standing rigidly at attention is a severe test of the efficiency of the mechanisms responsible for the venous return to the heart.

Muscular tone is dependent on many factors—adequate blood supply, absence of excess of fatty upholstery, a regular arrival of motor impulses to the muscle controlled from higher centres and a cooling mechanism nicely co-ordinated to the needs of the moment. It is easy to demonstrate that faulty heat loss lowers tone. The avenue by which heat is lost is apparently unimportant, but, unless under the artificial conditions of the laboratory, where even loss by radiation can be made the effective sole method of losing heat, the evaporation of moisture from the skin is the usual limiting factor. Several investigators have shown that the phenomenon known as 'second-wind', by which a runner experiences a sudden relief from the agony of breathlessness and the leaden drag of weary muscles, is accompanied by sweating. When this occurs, alveolar carbon dioxide falls, the urgency of breathlessness fades, the head clears and the muscles act with renewed vigour.

Measures of Fitness. Three means of measuring fitness are thus indicated, and they are interrelated: (*a*) Tests of recuperative efficiency. The ability of the cardio-respiratory mechanism to return to normal functioning within a limited time after exertion. (*b*) The ease of heat loss under specified conditions. (*c*) The value of muscle tone.

(*a*) Tests such as Goodall's, Crampton's, Foster's, McCurdy's and Schneider's, which depend on arbitrary scoring for rise of pulse rate, blood-pressure and respiration rate after exercise, and scoring for the length of time for a return to pre-exercise levels, have a very low coefficient of reliability. Schneider's is the best, with $r = 0{\cdot}4$. McCloy prefers to measure alterations in diastolic pressure and pulse rate on standing erect after lying supine. For this r was between 0·8 and 0·9 in a limited study of healthy and convalescent golfers.

Turner's test, which depends on the cardio-vascular reactions during standing absolutely still for 15 minutes, has a coefficient of reliability of above 0·9 for adults but yields anomalous results with boys. In Schneider and Crampton's studies of pre-adolescent boys, the boy proved least fit by all other tests was the sole survivor at the end of 15 minutes' standing (with a pulse pressure of 8 mm. mercury !). The others had either given in or had fainted.

The rate at which the oxygen debt is repaid may be used as an index of physical solvency. The fit subject either pays cash to close the transaction or demands short credit. The percentage of the total debt liquidated during 3 minutes after the cessation of exercise is, in the case of the unfit, about 30, while the same subject, in condition, may have discharged more than 60 per cent of his debt. The drawback to the employment of tests of recuperative power is the possibility of overstraining the vaso-cardiac mechanism in the unsound.

(*b*) No large series of experiments has yet been planned to gauge the reliability of this test of efficiency.

(*c*) The value of muscle tone may be determined in various ways. Coffey, Barnum and Henderson used the knee-jerk as an index of tonus. Even when absolutely uniform strokes of the hammer are applied to the patellar tendon of a co-operating subject, variable degrees of the extent of kick are obtained with successive stimuli. It is a useful method to demonstrate the gross alterations for which these workers used it, but, principally because it requires a trained subject for accurate results, it is not of general utility. The direct reading of intra-muscular pressure is awkward and somewhat unpleasant for the subject. Several attempts have been made to link creatinine excretion with muscle tone.

Noël Paton, in his presidential address to Section I at Bournemouth in 1919, put forward the suggestion that the maintenance of muscle tone (and hence of physical fitness) depended in part on the presence in tissue-fluid of small quantities of guanidine or its methyl derivative. He showed unequivocally that muscle, either of warm- or cold-blooded animals, increased in tone when minute amounts of the salts of this base were administered. Since then much work has been done to elucidate this problem. Sullivan was able to estimate the urinary guanidines in cases of progressive muscular dystrophy before and during treatment. As the cases improved, under glycortal medication, simple guanidines disappeared from the urine. More recently, Minot has successfully treated patients suffering from this disease by oral administration of guanidine hydrochloride; and Dewar, working in my laboratory, has confirmed this (using the tasteless carbonate). Unfortunately, exhaustive search has failed to find a reliable method for the estimation of urinary or blood guanidine, and so, as a test of tone, the determination of the simple guanidines is, at present, unavailable.

The sympathetic control of muscle tone has been the subject of many investigations and much controversy. There is a wealth of indisputable evidence that the anatomical sympathetic system plays, at best, a minor part in the direct maintenance of muscle tone, and no one now holds the views of Hunter or of Royle. On the other hand, the work of the Orbeli school, amply confirmed by later experimenters from other laboratories, points to the influence of adrenergic nerves on the neuromuscular mechanism. This influence is shown more clearly when the action of the vasoconstrictor fibres is removed by poisoning with ergotoxine. This may be taken to mean that the main function of the sympathetic in the maintenance of muscular tone lies in ensuring effective vasodilatation of the muscle capillaries brought about through the so-called 'nutrition reflex'. The fit man, with good muscle tone, soon stops the drain on the blood supply to skin and viscera, while the unfit keeps the pallor of skin for some time and may even show signs of acute digestive upset. One may, therefore, test fitness by estimating the degree (amount × time) of the deprivation of the skin of moving blood.

The responsiveness of the sympathetic arm of the reflex arc depends on the functioning of the cortices of the suprarenal glands. This pair of ductless glands with a long ancestral history is absolutely necessary for life and is affected by any undue strain on the reserves of strength. The will to endure, to keep going on, is mental, but the power to force an unwilling body to obey the order of the mind, to exert its last ounce and not die in the last ditch, depends, in the end, on the adequacy of the secretory mechanism of the cortices suprarenales. Animals with grafts of cortical tissues and no medullæ act as normals. Injection of cortical extract to completely adrenalectomized rats restores voluntary activity to an extent depending on the amount of cortin given. Hypertrophy of cortical tissues follows exercise in the rat. "Possibly", says Dill, "one of the effects of training is to increase the secretory activity of the adrenal cortex."

The sequelæ of severe muscular exercise under conditions where cooling is inadequate differ only in degree from those of cortical insufficiency, that is, loss of muscle tone, increase of blood potassium and lowering of blood sodium both absolutely and relatively. The loss of tone may be due to imbalance between the metallic ions as well as to exhaustion of cortical supplies, as it may be mirrored in normal subjects by administration of salts of potassium.

PSYCHOLOGICAL TESTS

The fit man carries on his work and his play without an unpleasant degree of fatigue, and so his industrial output may be taken as a measure of his fitness. The amount of work done or the goodness of the work done depends not only on the physical state of the worker but also on the state of his mind. It is well known that work which is in itself pleasant or leads to pleasure as a more or less remote result is carried out with an efficiency lacking in more formal performances or in forced work. L. Hill, Gillespie and many others have shown that the initial cardiac acceleration followed by peripheral and splanchnic vasoconstriction leading to an increased venous return to the heart with consequent cardiac retardation and increased output is mainly psychical in origin. If the work is uninteresting or the movements passive, these preparatory circulatory changes do not take place and the organism as a whole is thus less fitted to do work. Investigations involving treadmills, stationary running, bicycle ergometers, etc., may thus fail to reveal accurately the efficiency of a subject because of the more or less complete lack of interest of the work once the novelty has worn off. The performance becomes a routine and the efficiency consistent but low. On the cessation of the mental effort, the tone of muscle falls, the peripheral and visceral vasoconstriction passes off and output falls. One of the conclusions, drawn from the results of many exhaustive investigations made in the United States and in Great Britain, is that good sociological conditions are of paramount importance if good work is to be expected. Even apparently trivial improvements in amenities lead to increased output. For example, the average output of relays per hour in the Western Electric factory at Chicago of 55·7 when lunch was provided by the management, rose to 66·4 when the employees supplied their own lunch. This rate was maintained over two periods of 31 weeks (of the observation period) and was a record (Whitehead quoted by Dill). Hitler realized this principle, in theory at least, when he instituted his 'Strength through Joy' movement.

Value of 'Stunt' Tests. Cathcart places great value on the ability to react rapidly and accurately to changes in the environment. Efficiency in this can be tested by presenting the subject with exercises which demand new co-ordinations as well as motor activity with a performance both easy and graceful. This type of test, as outlined by Brace, McCloy and others, has a coefficient of validity of more than 0·8.

EXERCISE AND FITNESS

What, then, can be said of the effect of exercise in maintaining fitness? The Committee of the Health Section of the League of Nations is rather despondent on this matter. It says, "Up to the present, methods and systems of physical education have not produced any clearly demonstrable effect on the health of the masses, doubtless because the present state of our knowledge is not as yet sufficient to enable us to base them on accurate scientific data" (1938).

Properly designed exercises, carefully controlled, can be used to correct faults of carriage, to eliminate uneconomic muscular actions and fit the mildly dysplastic to take their place without shame among the euplastic. The danger of such exercise lies in any attempt to create an 'ideal' posture, etc., which has no physiological foundation.

Exercise carried on without strain or undue fatigue keeps the body in tone; and some exercise is considered beneficial to those engaged in sedentary occupations especially, as it increases the venous return to the heart and prevents stagnation in the blood reservoirs and lower limbs. The group of experts of the Commission on Physical Training were therefore enjoined "to determine the minimum amount of physical training required to ensure the normal health of the individual".

Exercise designed to 'build muscles' beyond the needs of that particular person merely leads to increased food intake, and when, because of age or lack of opportunity, the amount of exercise is decreased, fibrous and fatty degeneration and infiltration takes place. While it may be 'better to have lov'd and lost', it is certainly not better to have exercised and stopped.

Probably the main beneficial result of keep-fit classes and similar movements is the inculcation of a spirit of independence, personal confidence and pleasure in performance. Although "the healthy body works in silence" (Carrel), the fit person has a keen sense of the enjoyment to be obtained from suitable exercise. The physiological foundation of the exhilaration resulting from exercise—an exhilaration not entirely due to a decreasing handicap at golf or competitive improvement at other games—would be a suitable and profitable study for ambitious politicians and others.

While it is true that one cannot assess a man's efficiency until his whole life's story has been unrolled (and then it is too late to do anything about it), one should be able to establish norms related to age and sex. The recent Military Service Act provides an occasion for the audit of the nation's young manhood, and, provided suitable tests are applied by properly trained examiners, a beginning will have been made to the collection of facts and figures from which much may be learned.

There is no doubt as to the improvement in mental and physical fitness that results from wise physical training, co-operative effort and good feeding such as that obtained in military camps of the best type. Such training may go far towards reconditioning some of the youth of Great Britain. The American Department of Labour, in a report (1935) on two years' experience of civilian conservation camps, says, "Thousands of actual case records reflect the fact that the C.C.C. men have returned to their homes definitely benefited physically and mentally; their outlook toward the future is brighter, their sense of self-reliance and their ability to adjust themselves to economic conditions is stronger." To this tribute to wise and varied physical, mental and moral education one may add the results of a short experiment in effectively reconditioning a selected number of rejected recruits for the British Army: "My predecessor started a depot for training a limited number of men who were below standard and, as a result, . . . 576 of the 600 . . . have reached the full standard of fitness" (Right Hon. L. Hore-Belisha, Devonport, 1937).

While not in any way detracting from the importance of work of this type on men during late adolescence and early maturity, one may ask why the audit is not made earlier in the course of our national business of turning out citizens—taken early before the debit balance of wasted lives becomes so large that strenuous measures have to be taken to safeguard our interests. No factory the products of which were good, bad and indifferent would exist long before the shareholders were demanding an inquiry and a change of directorship. Our national strength lies in our men and women and not in the machines that they tend or the battleships that they man. To be really great a State must have citizens fit in body and also in mind. "The health of the intelligence and of the affective sense, moral discipline and spiritual development are just as necessary as the health of the body and the prevention of infectious diseases" (Carrel).

To ensure this would cost money, but so does radium. The chief use of this rare element is to prolong the life of the aged; should we not be equally ready to foot a bill which would make young lives more fit to bear hopefully and without undue strain the heavy burden their ancestry has laid on them ?

OBITUARIES

Mr. H. P. Hollis

ASTRONOMICAL circles will miss the familiar figure of H. P. Hollis, who died on August 7 at the age of eighty-one years. Hollis was born on January 9, 1858, and was educated at Westminster, from which he went to Jesus College, Cambridge. He took his degree in 1880 and in the following year was appointed to the post of assistant at the Royal Observatory, Greenwich, where he remained for forty years, retiring in 1920. His work at first was connected with the regular astronomical observations with the transit and altazimuth instruments; but later he took part in the measurement and reduction of solar photographs. Among his various other activities must be mentioned his work in the determination of the difference of longitude between Greenwich and Paris. The reductions of the observations made in 1892 and also in 1901 were carried out under his directions. In 1896 he was promoted to a higher grade and took charge of the work of the Astrographic Chart and Catalogue. A record of his twenty-four years in this department is found in the two volumes which give the positions of the stars as measured on the photographs and also the photographic reproduction of the chart plates, as well as in the two other volumes supplementing these results.

Outside his professional duties at the Royal Observatory, Hollis took a keen interest in astronomy and was always pleased to assist the amateur in his difficulties. For some years he contributed very useful information to the tyro by his letters to the *English Mechanic*. He was an original member of the British Astronomical Association founded in 1890, and was president during 1908–9. In addition to serving on the Council at various times, he represented the Association on the Geophysical Committee of the Royal Astronomical Society, and contributed a number of valuable papers to the *Journal* of the Association.

In 1884 Hollis was elected a fellow of the Royal Astronomical Society, and served on the Council from 1909 until 1911. A number of papers appeared under his name in the *Monthly Notices* and the *Memoirs*; the last of these was in the *Monthly Notices* 79, 36 (1918), in which he discussed the magnitudes of Nova Aquilæ, deduced from the photographs which had been taken at the Royal Observatory, Greenwich. He edited the *Observatory* magazine from 1893 until 1912, and for many years was astronomical correspondent to *The Times*, to which he contributed the well-known article, "Stars of the Month". In 1910 his work, "Chats on Astronomy", was published. This was written in a popular style and was specially useful to beginners interested in astronomy.

Hollis maintained his interest in astronomy to the end, in spite of his physical disability. He seldom missed any astronomical meetings, and his mental faculties seemed unimpaired.

In 1882 he married Clara Susanna Clark, who predeceased him in 1932. Two sons and a daughter survive him.

Prof. L. Lévy-Bruhl

We regret to record the death of Prof. L. Lévy-Bruhl, the distinguished French philosopher and ethnologist, which took place in Paris on March 12 last at the age of eighty-one years.

Lucien Lévy-Bruhl was born on April 10, 1857. For long he had held a foremost place in the development in France of philosophical and sociological studies. He was appointed professor of philosophy in the Sorbonne in 1899 and occupied that chair until 1927, when on his retirement he was appointed honorary professor. He was elected a member of the Academy in 1917. He edited the *Revue philosophique* for many years. During 1927–30 he was president of the Institut française d'Anthropologie, of which he was one of the founders and a constant and enthusiastic attendant at its meetings so far as the calls of a busy life allowed. He had travelled widely, and had made the voyage round the world. He delivered courses of lectures in the universities of many countries outside France, including Egypt and both North and South America.

Although Prof. Lévy-Bruhl was the author of a number of profound works on philosophical topics, he was best known to a wide public in both France and England for his studies of primitive and 'savage' mentality, several of which appeared in English translation, while in France they served to introduce the psychological aspects of social anthropology to a wider circle than is usually attracted by scientific studies. In this field his principal or best known works are "Fonctions mentales dans les Sociétés inférieures" (1910), "Mentalité primitive" (1922), and "Surnaturel et la Nature" (1930). In these and others of a kindred character he developed his theories of primitive mentality as belonging to a mystic and prelogical stage of thought in a graceful and lucid style and with the support of a full documentation of facts.

Mr. Clifford Chaffer, O.B.E.

MR. CLIFFORD CHAFFER, superintendent of the Admiralty Research Laboratory, died suddenly on June 26 at his home at Weybridge, Surrey, at the early age of fifty-four years.

Mr. Chaffer was born on October 25, 1884, at Morley, Yorkshire, and, after going to the Wheelwright Grammar School, Dewsbury, became a scholar of Peterhouse, Cambridge, where he remained from 1903 until 1907. He was 18th wrangler in 1906 and took the National Science Tripos in 1907. On leaving the University he held mathematical masterships for a number of years.

In 1916 Mr. Chaffer was appointed a temporary Instructor Lieutenant in the Royal Navy, and after service at sea he was posted to the Admiralty Compass Department. On demobilization in 1920 he accepted an appointment on the civil staff of the Compass Department where he continued to serve until 1936 when he was transferred to the headquarters staff of the Department of Scientific Research and Experiment at the Admiralty.

He was appointed to the Admiralty Research Laboratory as superintendent in 1937 and in this position his clear judgment, power of recognizing the essential features of the problems with which he was called upon to deal, and his ability to inspire the staffs with his personal keenness and single-minded devotion to duty were of the greatest value in a time of unusual stress.

Baron Joji Sakurai

DR. MARIE STOPES writes: "All that Prof. Donnan says in the first paragraph (NATURE, Aug. 5, p. 234) of his obituary notice of Japan's greatest scientist I should like to endorse from personal experience while an honorary member of the professor's common room in the Imperial University, Tokyo. However, no obituary would be complete without mention of his spiritual and literary sensibilities. These were partly revealed by his interest and proficiency in the profound medieval religious plays 'The Nō' which he and I translated together into English and published under the title 'Plays of Old Japan'. The then Japanese Ambassador, Baron Kato, wrote that they 'placed Western students of Japanese art and literature under a debt of gratitude'. Prof. Sakurai, who was a most faithful friend, was in Great Britain for the Coronation of King George VI, and I had the privilege of viewing it with him. He was one of the few scientists who made one revere him".

We regret to announce the death of Prof. E. Westermarck, formerly professor of sociology in the University of London, aged seventy-seven years.

NEWS AND VIEWS

Sir Richard Gregory and the British Association

SIR RICHARD GREGORY, who has been elected president for the coming year of the British Association, has been connected intimately with its activities for the past forty-three years. Both on the Council and upon sectional committees, his wide knowledge of men and their achievements, his tact and his infinite capacity for work have made his services of special value to the welfare of the Association and the progress of science. At the creation of Section L (Educational Science) in 1901, Sir Richard was one of the secretaries, and he has remained in the closest touch with the Section since that date, serving as president in 1922. No one has done more to keep the Section alive to the more pressing problems of education, and he brought to it the men and women most competent to advise on the special topics of the year's programme. He has also taken a vital part in the work of the committees of sections appointed to inquire into special problems. These committees often comprise a long list of distinguished names, but experience shows that the real work of gathering information and drafting the report falls upon comparatively few. Sir Richard was invariably one of these few. In the past thirty-eight years, he has served upon more than twenty such committees either as chairman, secretary or ordinary member, and it must be remembered that these committees run for several years and report annually.

DURING the early years, Section L was much concerned with the place of a training in scientific method in the curricula of schools of all grades, and devoted itself mainly to scholastic problems. During this period, Sir Richard's services were invaluable. Among the more important reports for which he was in large measure responsible were those on practical and scientific studies and the position of science in the school certificate examination, with which was associated a report upon the influence of examinations on curricula and teaching methods. The first of all these reports, on the teaching of elementary mathematics, has affected profoundly the methods of mathematical teaching in schools of all grades. In later years Section L has been more concerned with the social, industrial and cultural relations of science in school education, and here again Sir Richard's wide knowledge of movements and their leaders has enabled the Section to bring to its assistance those most able and willing to help. He himself gave much time to the reports upon the mental and physical factors in education, to the many aspects of adult education, the effects of the free-place system in secondary schools and to training for overseas life. At the Nottingham meeting Sir Richard induced Mr. H. G. Wells to give his stimulating and provocative address on the informative content of education, which gave rise to a valuable report. Sir Richard was also chairman of the Conference of Delegates of Corresponding Societies in 1921.

No mention has been made thus far of Sir Richard Gregory's connexion during the past forty-five years with NATURE, from the editorial chair of which he retired at the end of last year. But it will be easily recognized that much of his work for Section L was intimately bound up with his wider interests. His zeal for the promotion of scientific research, its popularization and its application to everyday life was well shown when he offered a platform in NATURE early last year for the expression of opinions on the desirability of providing for more direct contact between men of science and public affairs, a movement which came to fruition in the establishment at the Cambridge meeting of the British Association of the new Division for the Social and International Relations of Science, with Sir Richard as its first chairman. During the many years when Sir Richard directed the policy of NATURE, he demonstrated time and again his belief in the mission of science as an instrument for the promotion of social, intellectual and industrial progress, and his election as president of the British Association sets a seal of approval on the action of the Association in forming the new Division. The Association may be assured that its objects, as set forth by its founders, and in particular, two of them, namely, "to obtain a greater degree of national attention to the objects of science, and a removal of those disadvantages which impede its progress", are safe in the hands of its new president.

Recruiting Men with Technical Qualifications

THE Ministry of Labour announces that technical committees associated with University Recruiting Boards have been set up to deal with offers of service from men less than twenty-five years of age with qualifications in engineering, chemistry, metallurgy, physics, the biological sciences and mathematics, in order that they may be allocated to an appropriate form of national service. The committees will sit in all cities with universities or university colleges in Great Britain and Northern Ireland, and applications, which should be made in the first instance to a local office of the Ministry of Labour, will be referred to the technical committees and the University Recruiting Boards. This offer is open to men who are starting on their final year of a degree course, or already hold a university degree in any of the following subjects: engineering, chemistry, metallurgy, physics, the biological sciences (including agriculture) and mathematics (including statistics); and to men who are starting on their final year of study or already hold a Higher National Diploma or Higher National Certificate in mechanical or electrical engineering, or the associateship of the Institute of Chemistry.

War Agricultural Committee

THE Minister of Agriculture and Fisheries has appointed a War Agricultural Executive Committee for each county in England and Wales and has made an Order (The Cultivation of Lands Order, 1939) authorizing these committees to exercise on his behalf certain powers conferred on him by the Defence Regulations for the purpose of increasing home food production in time of war. In a Circular Letter to the committees, the Minister states that they will be given as free a hand as possible to proceed as a matter of urgency with all possible steps to increase the production of foodstuffs in their areas. Their immediate task is to see that additional land is brought under the plough with all speed. The aim is to obtain for next year's harvest an increase of about 1½ million acres in the tillage area in England and Wales compared with the acreage in June last. Each county has been allotted its share of this total, and the committees have been urged to see that every effort is made to complete their allotted tasks—and, if possible, to exceed them. The committees have already been holding informal meetings and have made good progress with their preparatory work.

Roman Temple at Albury, Surrey

ROMANO-BRITISH studies are greatly indebted to the Surrey Archæological Society for the work of excavation and conservation which has been carried out on the site of the Roman temple on Farley Heath, Albury, Surrey, by A. W. G. Lowther and R. G. Goodchild on behalf of the Society. The complete plan of the building has now been traced, and marked out by stones from the original structure, bedded in concrete. The site has been known for a long time. It attracted the attention of Elias Ashmole; and in 1670 and 1847 it was despoiled of much of its stone. Little, however, was known of its structure or its relation to surrounding buildings, if any. Recent excavation has shown, it is reported in *The Times* of August 18, that the temple consisted of a simple cella, or shrine, measuring 18 ft. internally, and surrounded by a corridor, or veranda, 8 ft. wide. It has been too much damaged for any details of the architecture to be known, but red tesserae and red wall plaster hint at the character of the internal decoration. It stood within a polygonal wall, approximately 240 ft. in diameter, which probably was intended to demarcate the sacred enclosure. An inner enclosing wall has been found on the north side. Few smaller antiquities have been found in the recent excavations, the most important being a fragment of a terra-cotta "votive lantern", similar to those found at Ashstead, Surrey, and Verulamium. The ground had been too thoroughly turned over by previous diggers to make it probable that many of the smaller class of objects would be found. Further, the excavations of 1848 had provided a rich spoil—more than 1,000 coins, mostly Roman, but including some rare British in gold and silver, and numerous enamelled brooches, while a thin strip of bronze, crudely embossed with human and animal figures, has since been identified as a pagan priest's ritual sceptre. The foundations of the temple were of local ironstone and chalk from the North Downs, but the superstructure was of Bargate sandstone. Wealden clay had been used for the tiles, baked, in all probability, in the tile-kiln discovered in 1936 in Wykehurst Farm, Cranleigh, four miles away.

Archæological Explorations in the United States

A DETERMINATION to limit public expenditure and opposition to the President in the United States of America have recently eliminated most of the intellectual activities which had been subsidized out of Federal funds in the desire to stimulate prosperity by State aid. Archæological investigations in the field, however, so long as they worked within the States, have survived attack owing to the fact that they provide occupation for a considerable number of the unemployed. This consideration does not affect expeditions working abroad and in the Old World, and these have had to be curtailed on the ground of economy. Nearly one hundred archæological expeditions, it is reported by Science Service of Washington, D.C., have taken the field in the course of the present summer; and of these, thirty-two in twenty-two States are financed as part of the W.P.A. programme, the Government supplying the labour—2,500 men and women in all—for excavation work under the direction of representatives of museums, universities and scientific institutions sponsoring the respective expeditions. Two investigations in particular have been made possible by the advantageous conditions. Of these, one is a combined effort on the part of the Universities of Montana, Wyoming, and other of the south-western States to find evidence of the line of advance of the earliest immigrants into America through the Siberia-Alaska gateway towards the south-west. The other will make a rapid and intensive examination of the mounds and other relics of early occupation in the vast region in the States of Tennessee, Alabama and Texas, which is marked for inundation when the dams of the Tennessee Scheme of water supply are built. It is hoped that it may be possible to trace the relation of the cultures of the Mississippi Valley to those of the south before it is too late, and the evidence disappears for ever.

Excavations at Caerleon

FURTHER excavations on the site of the Roman fortress of Caerleon-on-Usk have been necessitated by building development on two acres at the north-east angle. Evidence for the defences here, it is reported by Lady Fox, who directed the excavation on behalf of the Caerleon Excavation Committee (*The Times*, Aug. 5), comprised the primary clay bank and ditch of the occupation by the Second Augustan Legion in A.D. 75, and the foundations of the stone walls and one of the internal turrets set up about A.D. 100, when the internal early timber buildings were reconstructed in stone. The construction of the rampart roadway, which provided access throughout the circuit of the fortress behind the ramparts, was examined. A block of barracks, set in pairs, back to back, and providing accommodation for soldiers, with more spacious quarters for the centurions, was found to be in plan similar to those excavated in the south-west corner of the fortress in 1926–9. A coin of Nerva confirmed the date of their erection. Occupation by the Second Legion on this occasion appears to have been short; but in the third century the barracks were thoroughly renovated at a date indicated by the stamp "Leg. II Aug. Anto." as A.D. 212–222. Relics of the latest occupation, not necessarily of a military character, were found in the centurions' quarters, where a tile hearth had been built over a destroyed partition wall, and the moulded base of a column, upside down and partly sunk in the floor, appears to have served as a gaming-table, as several counters were found around it. The associated layers contained fourth century coins and pottery of a late type. In all, 70 coins were found and 90 legionary stamped tiles. Pottery was not abundant, but the most interesting find was a hoard of five gold coins, ranging from two of Nero, A.D. 55 and 61 to Titus and Domitian, A.D. 74 and 73, which was found concealed in a barrack floor, and possibly represents the savings of a soldier, which was left behind when the legion was ordered north.

Health Activities of the Rockefeller Foundation

THE annual report for 1937 of the International Health Division of the Rockefeller Foundation, recently published, gives an account of the projects carried out under the auspices of the Health Division by members of its staff. Virus agents of yellow fever, influenza and other diseases, and certain proteins, including visual purple, have been studied by the use of an analytical ultracentrifuge. By means of a cultured yellow fever virus, a vaccine has been produced with which some 60,000 persons have been inoculated, mostly in Brazil, the results of which show that a practicable safe method of large-scale immunization against yellow fever is now available. Studies on the epidemiology of the jungle form of yellow fever have also been pursued. Tuberculosis, particularly in Jamaica, hookworm disease in Egypt and the United States, and malaria and its mosquito vectors in various countries, are other subjects that have been investigated. In addition to research work, the Foundation renders financial aid to State and local health services and to health education in all parts of the world. The report, which is very readable, includes several plates illustrating the work carried out.

The International Seismological Summary

THE International Seismological Summary for July, August and September 1933 has just come to hand, containing details of the calculations of the initial times and epicentres of 169 earthquakes. Sixty-eight of these epicentres are new and 101 are repetitions from old epicentres, showing the tendency of earthquakes to recur from the same epicentre. Included in the 169 earthquake shocks are 15 which had a focal depth below normal, the deepest being that of August 29, 1933, with epicentre 11·0° S., 69·5° W. (in Bolivia near its junction with Peru and Brazil) and focus 0·085 of the earth's radius below normal. Twelve of these deep focus shocks had their epicentres between 45·4° N., and 20·5° S. latitude, and between 131·5° E. and 170·0° E. longitude, thus showing the deep-seated instability of this region of the earth which has Japan in its north-west corner.

Milk for Mothers and Children

A SCHEME was prepared a short time ago by the Milk Marketing Board and approved by the Minister of Agriculture and Fisheries for the supply of cheap milk to local authorities, and was outlined in a circular issued by the Ministry of Health (Circular 1840. H.M. Stationery Office. *3d.* net). The aim of the scheme is to enable expectant and nursing mothers and children under five, who cannot afford the full retail price for the milk they need, to obtain a pint of milk per head per day either free or for not more than twopence according to family circumstances. Those wishing to receive milk under the scheme will have first to apply to the local authority and they will then be told whether they are eligible to receive the supply. When authorized, they will ask an approved dairyman to deliver at their home the milk to which they are entitled.

Announcements

THE remainder of the meetings of the British Association which began in Dundee on August 30 were cancelled on September 1. Most of the members present left Dundee on that day.

THE French Academy of Medicine has awarded the Grand Prix Prince Albert I de Monaco to Jules Lefèvre, for his work on biology during the last fifty years.

ON the occasion of the jubilee of the Paris Pasteur Institute the scientific and executive committees of the Institute have awarded the gold Pasteur Medal to Dr. H. Plotz, of New York, and Prof. A. Saenz, of Montevideo, for their contributions to science.

IT is announced in *Aesculape* of May that three new chairs for the history of medicine have been founded in Italy, namely, at Florence, Turin and Sienna, while corresponding chairs in Rumania have been abolished.

DR. W. JUNK writes from The Hague to point out a mistake in Dr. W. T. Calman's review of the British Museum reprint of Linnæus's "Systema Naturae" (NATURE, August 12, p. 269). The tenth edition was not, as there stated, the last published during Linnæus's lifetime. The twelfth edition began publication in 1766, twelve years before the death of the author.

ALL the poisonous snakes and insects in the Zoological Gardens of the Zoological Society of London have recently been destroyed. Several of the more valuable animals have been sent to Whipsnade. The Zoo is again open to the public.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 486.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Forces Associated with Heat Flow in Helium II

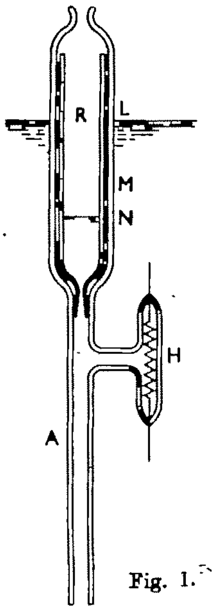

Fig. 1.

IT was discovered some time ago[1] that when heat flowed in helium II down a narrow capillary or through a tube filled with powder, liquid was forced up the tube in the opposite direction. It was considered at the time that the phenomenon, which has been called the 'fountain effect', was associated in some way with the surface of the capillary or of the powder particles. Recent experiments by Daunt and Mendelssohn[2], who have proved the thermodynamic reversibility of the effect, have tended to confirm the idea that it is a surface phenomenon. The thermodynamic aspects of the effect have been treated in a recent paper by H. London[3].

It has now been observed that when heat flows downwards through capillaries of the order of 1 mm. in diameter, the liquid no longer rises above the bath-level, as it does in the fountain effect, but sinks below it. The depression in level has been interpreted as being due to a force which acts on the liquid in the centre of the capillary and which carries the liquid along in the direction of the heat flow. Thus the force associated with the flow of heat in helium II has two components, one a surface effect in which the liquid is forced against the direction of the heat flow, and the other a volume effect in which the liquid in the centre of the channel is forced in the direction of the heat flow. The two effects were observed simultaneously in the apparatus shown in Fig. 1. The reservoir *R* contained a co-axial tube which was drawn to a fine funnel at the bottom so that it fitted into a 1·45 mm. diameter capillary. The funnel opening was about 1 mm. in diameter, which left an annulus of roughly 0·2 mm. width between the mouth of the funnel and the capillary wall. Heat was supplied electrically in the coil *H*, and flowed down the capillary *A* to the bath. The annular reservoir was thus arranged to collect the surface component of the force, the 'fountain effect', whilst the inside reservoir indicated the volume effect, that is, the liquid which is forced down the centre of the capillary. When heat was flowing down the capillary, which was 15 cm. long, the bath-level

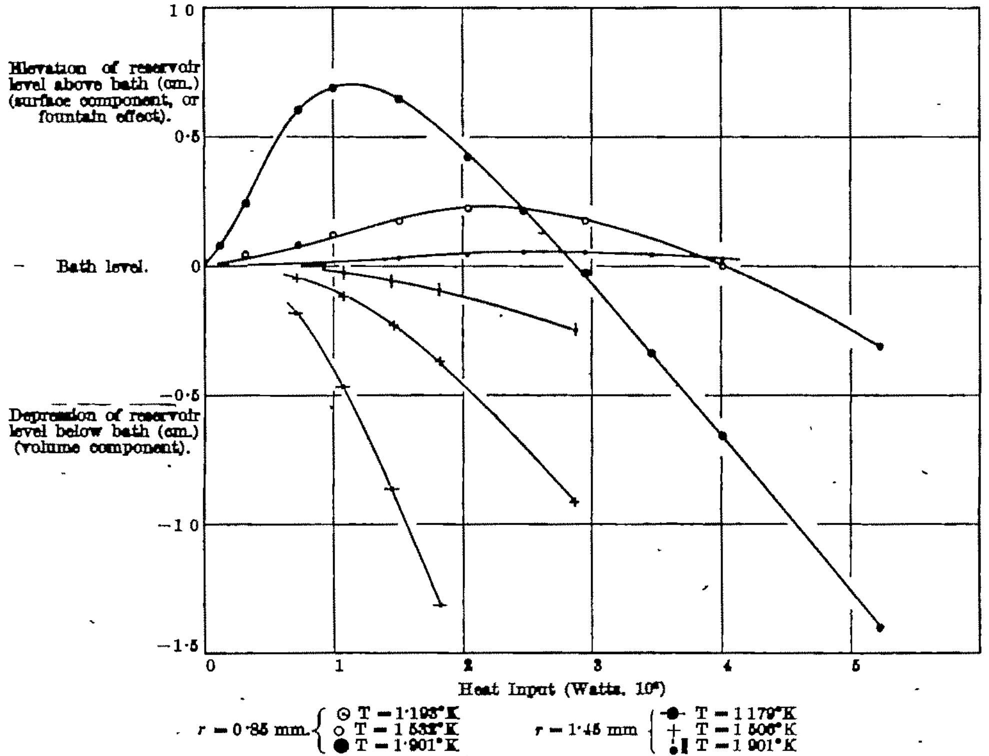

Fig. 2.

and the annular and inner reservoir levels assumed the relative positions L, M and N.

Fig. 2 shows the difference in level between the bath and the inner reservoir at different temperatures as a function of the heat input for two capillary diameters. The figure shows that in a capillary of 1·45 mm. diameter the surface effect is completely swamped by the volume effect, whilst in a capillary of 0·85 mm. diameter inversions take place. In the latter case the surface effect predominates for small heat flow whilst the volume effect predominates for large heat flow. The surface and volume components, therefore, do not appear to be symmetrical with respect to the bath level when considered as a function of temperature. In consequence, one does not find an intermediate capillary diameter which shows no net effect at all temperatures in helium II.

Although previous measurements made on a powder-filled tube indicate that the surface component is approximately a linear function of the heat flow, the nature of the present curves suggests that the surface component becomes saturated at high heat inputs. This would allow the volume component to predominate in a capillary where the total amount of surface is small. Further evidence of the saturation of the surface component was obtained from measurements on a powder-filled tube from which all but a few mm.[4] of the powder had been removed. Since both surface and volume components increase in magnitude for given heat input down to the lowest temperatures available, it would be interesting to find out the behaviour of the effects at still lower temperatures.

If both the surface components, as determined from previous measurements, and the present results (largely volume component) are plotted for constant heat input and as a function of the temperature, it is found that they both tend to constant values and not to zero as the temperature approaches the λ-point. The surface effect, however, when plotted as a function of temperature difference, does approach zero at the λ-point[4]. Incomplete measurements on the volume effect indicate that it also behaves in the same way.

The experiments described above help to confirm the ideas previously advanced[1,2] with regard to the fountain effect, namely, that it is associated with the surface of the channel. Although the surface component can be understood from F. London's[5] hypothesis of helium II, based on consideration of Bose-Einstein condensation phenomena, the volume effect presents a further complexity. Much more research will be necessary before a clear theoretical picture of helium II can be produced.

The Electric Quadrupole Moment of the Deuteron and the Field Theory of Nuclear Forces

THE discovery by Rabi and his collaborators[1] that the deuteron in its ground state possesses an electric quadrupole moment is of considerable theoretical importance, since it clearly shows that the forces acting between a proton and a neutron must to a quite appreciable extent depend on the spatial orientations of the spins of the heavy particles. It is well known that the vector meson theory of nuclear forces formally provides such a directional coupling, though of so strongly singular a type that it can only be given a definite meaning by taking recourse to some arbitrary cutting-off prescription. Now, Bethe[2] has recently examined the question how such a cutting-off should be performed, in a theory giving rise to charge-independent nuclear forces, in order to obtain the correct positions of the ground-level and the excited ^1S-level of the deuteron. He was led to the conclusion that, while the way in which the cutting-off is performed is of small influence on the results, the value to be assumed for the cutting-off radius depends critically on the combination of charged and neutral meson fields adopted: if one uses the symmetrical combination of meson fields suggested by Kemmer[3], the cutting-off radius should be chosen larger than the range of the nuclear forces, and a reasonable value of this radius can only be obtained if the meson field is assumed to be purely neutral. This last assumption amounts of course to giving up the remarkable connexions suggested by the symmetrical theory between the problem of nuclear forces and those of cosmic ray phenomena, beta decay and especially the magnetic moments of proton and neutron.

In view of this unsatisfactory feature of the vector meson theory, we should like to point out that the question of the quadrupole moment of the deuteron, as well as the whole problem of the consistency of the meson theory of nuclear forces in its present provisional form, takes a quite different aspect when, as already suggested in a recent note[4], pseudoscalar meson fields are introduced besides the vector fields in such a way as to cancel all strongly singular terms in the static interaction energy of the heavy particles. In such a theory, which necessarily involves the choice of Kemmer's symmetrical combination of charged and neutral fields to account for the charge-independence of the nuclear forces, no question of any cutting-off arises, provided of course the physical interpretation of the formalism is restricted in a way analogous to the so-called correspondence treatment of quantum electrodynamics. At first sight, however, it would seem as though the disappearance of the singular static interaction terms, which just contain the directional coupling of the vector meson theory, would leave no room for such an effect as the quadrupole moment of the deuteron. But it is most readily shown by the method of canonical transformation described in our previous note, that the interaction energy between the heavy particles involves, besides the static interactions hitherto discussed, further significant interaction terms, which represent a directional coupling of the character just required for the occurrence of a quadrupole moment in the ground state of the deuteron.

The non-static interaction terms just mentioned, which contain a factor of the order of magnitude of the ratio of the velocities of the heavy particles to the velocity of light, are also quadratic with respect to the fundamental constants determining the strength of the sources of the meson fields; in fact, if the constants referring to the four-vector and six-vector source densities of the vector meson fields, and to the pseudoscalar and pseudovector source densities of the pseudoscalar meson fields, are denoted by g_1, g_2, f_1, f_2 respectively, these interaction terms are proportional to the products g_1g_2 and f_1f_2. A straightforward calculation then shows that the resulting quadrupole moment of the deuteron contains the factor $g_1g_2 + f_1f_2$. The constants referring to the pseudoscalar meson fields are only restricted by the conditions that $|f_2| = |g_2|$ and that $|f_1|$ should not be very much larger than $|g_1|$ or $|g_2|$; the adjustment of the theory to the known energy spectrum of the deuteron fixes the order of magnitude, but not the signs, of g_1 and g_2. Thus, in contrast to the vector meson theory, in which the two cases studied by Bethe correspond to definite values of the quadrupole moment, of opposite signs and very different magnitudes, the theory discussed in the present note would be able to account for any sign and for a wide range of magnitudes of the effect in question. It does not seem possible at present to derive from the measurements an entirely reliable estimate of the effect, owing to the insufficient knowledge of the electronic wave-functions of the hydrogen molecule, which enter in such a derivation. Anyhow, the order of magnitude following from our theory, if we make, for example, the simplest assumption $f_1 = 0$, agrees reasonably well with the provisional empirical value given by Rabi and his collaborators.

A fuller account of the problems discussed in this note and in the previous one will appear in the *Proceedings of the Copenhagen Academy*.

Effect of Temperature on the Intensity of X-ray Reflections from Copper

IN a recent letter in NATURE[1], Prof. E. A. Owen and Mr. R. W. Williams have given results for the effect of temperature on the intensity of X-ray reflections from copper. They find that throughout the range of temperature from 290° to 840° A., the decline of intensity with temperature is greater than predicted by the usual Debye-Waller formula, $\exp. -2M$, where M has the well-known expression involving the characteristic temperature Θ which occurs in the Debye theory of specific heats, and that their results agree closely with a temperature factor of the form $\exp. -3M$.

The fact that deviations from the Debye-Waller formula occur at the higher temperatures is not surprising, but so large a deviation near room temperature would not be expected. An alternative explanation of the results would be that the value of Θ to be used in the expression for M is not identical with that given by specific heat data. Since M is approximately proportional to $1/\Theta^2$, it follows that instead of changing the numerical factor from 2 to 3, we may take

$$\Theta\ (\text{X-ray}) = \Theta\ (\text{sp. heat}) \times \sqrt{2/3} = 315° \times 0{\cdot}816 = 257°.$$

To test this result we have examined the intensities of reflections from copper at room temperature and liquid air temperature, using two methods to arrive at the temperature factor. (1) Using a mixture of copper and aluminium powders, we have measured the change in the copper intensities in terms of the aluminium intensities, the latter having previously been determined. (2) The second method is to use the relative intensities from the copper powder at the two temperatures and, with cubic metals, these data alone are sufficient to give the temperature factor. Method (1) is probably the more accurate but involves a second substance; method (2) is less accurate but eliminates any comparison substance.

Our results by the two methods are: (1) $\Theta =$ 310° Abs. (2) $\Theta = 297°$ Abs. The uncertainties in these figures are of the order of 4 per cent; that is, about ± 12°. Comparing these with the specific heat value, 315° Abs., we see that while there is a tendency for the X-ray value to be smaller than the specific heat value, there is no marked discrepancy.

Note added after writing the above letter. Prof. Owen and Mr. Williams have kindly informed us of their more recent work on gold, which has yielded results in close agreement with theory (see following letter). This result, considered in conjunction with our own measurements on copper at low temperatures, indicates that no abnormalities are to be expected for copper at higher temperatures, and we think that the suggestion which they make regarding the tarnishing of the copper is quite likely to prove correct.

Effect of Temperature on the Intensity of X-ray Reflections from Gold

IN a previous letter[1] we referred to some measurements that we carried out on the effect of temperature on the intensity of reflection of X-rays from copper, from which it was concluded that over the range of temperature from about 20° C. to 570° C., the intensity decreased with rise in temperature more nearly in accordance with the temperature factor $\exp.(-3M)$ instead of the factor $\exp.(-2M)$.

Looked at from another point of view, the characteristic temperature of copper, assuming the $\exp.(-2M)$ factor, works out to be 261° K., which is well removed from the accepted value of 315° K. The main difficulty with the measurements was to keep the surface of the copper untarnished, and to meet the difficulty the material was exposed to X-rays when it was maintained at a given temperature in an evacuated chamber.

Similar measurements have now been completed with gold, the surface of which can more easily be kept clean when maintained at high temperature. The results obtained with gold agree more closely with the $\exp.(-2M)$ factor, the characteristic temperature working out to be 161 ± 9° K. when the temperature of the material is 445° K. This is in close agreement with the characteristic temperature of 166° K. calculated by Debye from the elastic constants of gold and not far removed from the experimental values of 170° and 175° deduced respectively from specific heats at low temperatures and from electrical conductivity measurements. At higher temperatures the characteristic temperature of gold on the basis of the $\exp.(-2M)$ factor turns out to be somewhat lower.

It would be well, therefore, not to accept the results obtained with copper at temperatures above room temperature until further measurements have been made under more rigorous conditions.

Observations with Electromagnetic Microbarographs

Two electromagnetic microbarographs designed by H. Benioff to respond to pressure variations in the frequency range from five cycles per second to one cycle in thirty seconds approximately, and with sufficient sensitivity to record the natural unrest of the atmosphere, have been in operation at the Seismological Laboratory in Pasadena for approximately two years. These instruments were operated either at the same point with different characteristics, or at points separated by distances from several to more than 100 metres, with identical characteristics. In the short-period galvanometer combination the response is approximately proportional to the rate of change of pressure. For periods of 1 second, the sensitivity is such that 1 mm. deflection of the galvanometer corresponds to a pressure change of 1 dyne per $cm.^2$ approximately. The instruments respond to waves as well as to current variations. Discrimination between these two types of movements is made on the basis of their difference in velocity of propagation, the waves being propagated with the velocity of sound, while current variations are propagated with much smaller velocity.

The waves are produced either by natural causes such as earthquakes, surf, other unknown sources or artificial causes (aeroplanes, automobiles, dynamite blasts, gunfire). Waves produced by battleship target practice have been used by Gutenberg to calculate sound velocities and temperatures in the stratosphere. His results agree with those obtained in Central Europe and Novaya Zemlya. The natural waves have predominant periods of 4 sec. and 20 sec. to several hundred seconds, and are largest in winter. They have exhibited no correlation with microseisms.

Air currents produce irregular disturbances throughout the whole range of recorded frequencies. They are due either to ordinary wind or to convection currents resulting from heating of the ground by solar radiation, and ordinarily the two types are not distinguishable from each other in appearance on the records. Both types of movements can be recorded indoors, although under these conditions they are modified in amplitude and in frequency characteristics. They are absent on calm, overcast or foggy days. On clear, calm days convection currents are small in winter, when they are occasionally recorded here from approximately 10 a.m. to 3 p.m. In April and November they occur from approximately 10 a.m. to 4 p.m., and during June and July they appear from 7 a.m. to 7 p.m. Strong currents of either type produce strains in the ground rock as recorded by the strain seismograph. Sudden changes in the characteristics of short-period movements sometimes accompany the passage of a cold front.

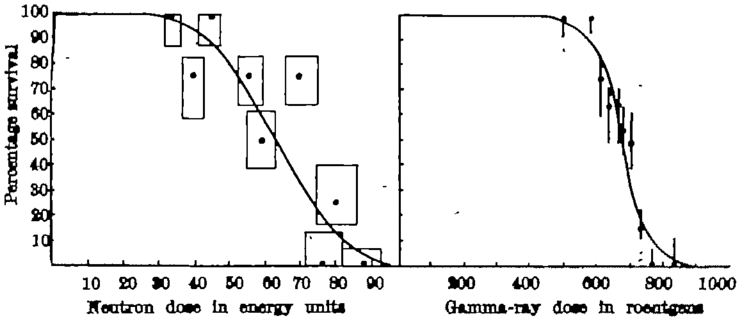
Comparison of the Lethal Effect of Fast Neutrons and Gamma-Rays on the Growing Tips of Broad Bean Roots

THE growing tips of broad bean roots have been irradiated by D-D neutrons (~ 2·9 Mev.) and by gamma-rays by techniques already described[1,2]. The duration of irradiation and the variation of intensity along the length of the root was approximately the same for both radiations. The neutrons were unaccompanied by gamma-radiation, and stray X-rays were excluded by 5 mm. of lead surrounding the specimens. The dose was measured and converted into energy units in the manner already described[1,2].



SURVIVAL OF BEAN ROOTS EXPOSED TO NEUTRON AND GAMMA-RAY ENERGY MEASURED IN COMPARABLE UNITS.

The mortality curves for gamma-rays and neutrons are shown in the accompanying figure. The apparent difference in shape between the two curves is not considered to be established in view of the magnitude of the probable errors represented by the rectangles. Individual points on the neutron curve represent the result of irradiating batches of from four to twelve beans. The probable errors of these points were estimated as follows. The probability of observing a certain mortality q in an experiment with N beans, for which the true probability of death corresponding to the dose is p, is :

$$Lt_{x\to\infty}\ {}^{Px}C_{qN} \times {}^{(1-P)x}C_{(1-q)N}/{}^{x}C_{N},$$

which, for q constant, is proportional to

$$P^{qN}\ (1-P)^{(1-q)N},$$

Plotting this probability against p, and halving the area on each side of the maximum, we obtain the range of values of p within which it is a 50 per cent chance that the true value of p corresponding to the dose, lies.

It is evident that 50 per cent mortality is produced by 63 ± 6 energy units of neutrons, which may be compared directly with the value of 690 ± 35 roentgens of gamma-rays, since the unit of energy has been defined as the increment of energy per unit volume of water exposed to 1 roentgen of gamma-radiation. Neutron energy thus appears to be about ten times as efficient as gamma-ray energy in its lethal effect on bean roots.

We gratefully acknowledge the financial assistance of the British Empire Cancer Campaign, and the loan of radium by the Medical Research Council.

Note added in proof. We are advised by a statistician, "It is not correct to say there is a 50 per cent chance that the true value of p corresponding to the dose lies in the range found in the manner described above. This cannot be done without the use of 'inverse probability', which is not justifiable in such cases as this". However, we have treated the data in the manner described on p. 243 of "Biological Effects of Radiation", Vol. 1, Duggar, with the same conclusion regarding the 50 per cent mortality dose.

Formula for the Change of Velocity of Sound with Temperature

THERE appears to be no simple expression which satisfactorily represents the velocity of sound in air over normal ranges of temperature.

The formula

$$v = 331 \cdot 5 + 0 \cdot 56\, t,$$

in which v is the velocity in metres per second at a temperature t° C., is accurate to three significant figures between − 40° and 100° C. Thus, at 100° C., the expression gives 387·5, which is correct to 0·1 per cent, and at − 40°, 309, which is the value obtained from the Greely and Parry Antarctic measurements.

Action of Copper Salts on Emulsions Stabilized by Sodium Oleate

DURING experiments on the effect of addition of electrolytes on emulsions of xylene in water stabilized by sodium oleate, we noticed that the xylene thrown out by copper salts was a clear, bright green or blue colour. The same colour was obtained if benzene, even the purest benzene, was used instead of xylene. On adding a quantity of copper salt equivalent to the sodium oleate present in the emulsion, benzene began to separate immediately and a certain amount of inverted emulsion was also formed, which, however, broke after some time. The separated water contained copper. On evaporation of the benzene a dark green, waxy solid was obtained, which on analysis gave a ratio of copper to oleate of 1 : 3·4 and contained some sodium. Dilute solutions of this solid in benzene were blue, more concentrated ones a bright emerald green.

Copper oleate prepared by the interaction of equivalent quantities of copper sulphate and sodium oleate in aqueous solution was, when first precipitated, insoluble in benzene. After allowing it to stand for some time it could be filtered off and obtained as a much paler green, waxy solid, which on analysis gave a ratio of copper to oleate of 1 : 2·05. After it had been kept for some time this solid would dissolve in benzene, presumably because it had lost some water, to give a solution identical in appearance with that obtained when breaking emulsions. Freezing point measurements, however, showed that these solutions were not identical. Copper oleate prepared in aqueous solution caused no depression of the freezing point of benzene (compare the work of Bhatnagar, Kapur and Hussain[1] on magnesium and zinc oleates) whilst the substance obtained on breaking an emulsion did depress the freezing point. Freshly precipitated copper oleate can be made immediately soluble in benzene by the addition of sodium oleate or oleic acid.

Now when our emulsion was completely broken, all the oleate was dissolved in the benzene, but not all of it as ordinary copper oleate, the ratio of copper to oleate being 1 : 3·4. Therefore one might expect that it would not be necessary to add a quantity of copper salt fully equivalent to the sodium oleate present in order to break the emulsion, but only 2/3·4 or 59 per cent of this amount. This expectation was not fulfilled—addition of this quantity of copper salt threw out only about one third of the benzene. We therefore conclude that the copper ion experiences some resistance to penetration to the oleate at the benzene-water interface, perhaps due to strongly attached sodium ions of the inner portion of the diffuse section of the double layer forming a practically continuous protective sheath of bound water around the benzene droplet.

The power of cations to overcome this resistance should be greater the less they are held back by their affinity for the aqueous phase, which affinity is indicated by their position in the lyotropic series. In our experiments on the partial breaking of emulsions by a number of electrolytes, we have found that the order of effectiveness of a number of cations did follow this series; for example, calcium chloride was less effective than strontium chloride, which was less effective than barium chloride, and zinc sulphate was less effective than magnesium sulphate.

Cholinesterase and Electrolytes

WE have found some effects of electrolytes on the activity of cholinesterase, which may explain the well-known effects of these electrolytes on irritability.

A purified preparation of cholinesterase from horse serum free from electrolytes was used in these experiments. 1 mgm. of the dry enzyme preparation hydrolysed about 100 mgm. of acetylcholine per hour. The esterase activity was measured manometrically.

Calcium and magnesium ions act as activators and potassium ions as inhibitors of cholinesterase. The effects of added calcium, magnesium and potassium depend on the concentration of the substrate; they are more pronounced at low concentrations of acetylcholine. At a concentration of 0·5 per cent of acetylcholine, the activity of the esterase is increased about 30 per cent by calcium or magnesium and decreased about 15 per cent by potassium. At a concentration of 0·025 per cent of acetylcholine, the increase in enzyme activity by calcium and magnesium amounts to 100–150 per cent, the inhibition by potassium to about 40 per cent. The inhibition by potassium ions is abolished by calcium or magnesium. In a balanced medium, such as Tyrode solution, a decrease in calcium or magnesium has the same effect on esterase activity as an increase in potassium ions. All these effects are brought about by physiological concentrations of the electrolytes. The following table illustrates these facts.

HYDROLYSIS OF ACETYLCHOLINE.

0·05 c.c. purified cholinesterase preparation from horse serum; 0·5 mgm. acetylcholine; 2 c.c. 0·025 mol. sodium bicarbonate; 5 per cent carbon dioxide in nitrogen; 37° C.

Cations added (In form of chlorides).	Acetylcholine hydrolysed in 3 minutes
—	124 γ
0·24 mgm % Mg	174 γ
2·4 „ Mg	240 γ
0·44 „ Ca	180 γ
2·2 „ Ca	288 γ
400 „ K	73 γ
400 „ K + 0·72 mgm.% Mg	129 γ
400 „ K + 0·55 „ Ca	133 γ

The adjuvant actions of potassium on parasympathetic effects and the depressant actions of calcium (and magnesium) on such effects may be explained by the effects of these electrolytes on cholinesterase. Potassium, by inhibiting the esterase activity, would delay the destruction of acetylcholine and thus augment parasympathomimetic effects; calcium and magnesium, on the other hand, by activating the esterase, would accelerate the hydrolysis of acetylcholine, and thus antagonize such effects.

In the same way, the hyper-irritability in the various forms of tetany known to be associated with a low calcium or magnesium level, may possibly be due to a delayed destruction of the acetylcholine liberated by a motor nerve impulse at the nerve endings. The vasodilatation, observed in magnesium deficiency, may similarly be due to delayed destruction of acetylcholine liberated by impulses in cholinergic vasodilator nerves.

Can Rusts Fix Nitrogen?

Caldwell *et al.*[1] and Murphy[2] have shown that in wheat and oat plants infected with *Puccinia triticina* and *P. coronata* respectively, the amount of nitrogen, and of some other substances present, is greater than in uninfected plants. Gretschushnikoff[3] found that the rust he studied excreted urea and ammonia, which, he suggested, were removed by the host, since no correlation was found between the severity of the infection and the amount of ammonia and urea in the extracts of the rusted leaves. These facts suggest that rusts may fix atmospheric nitrogen just as some other fungi are believed to do.

Work begun in Cambridge in 1937 and continued in Portugal has suggested that the problem is worth investigating in some detail. The results of two experiments are given below. Six samples each of fifty plants of Jenkin wheat were grown on sand until the plants were showing the second leaf, and after cutting off the roots and grain the plants were washed in distilled water. Samples 1 and 2 were taken at the beginning of the experiment; samples 3 and 4 were placed with their cut ends in water and kept rust free; samples 5 and 6 were placed in water and inoculated with *P. graminis tritici*, race 27. Sample 4 was accidentally destroyed before the close of the experiment. Samples 3, 5 and 6 were collected twelve days after the experiment was begun. The plants when collected were dried and then analysed. The results of the analyses are given in the accompanying table.

	Rust-free	Dry weight in gm.	Absolute nitrogen per gm.
Initial control	1	1·2549	0·06604
	2	1·2858	0·06038
Final control	3	1·6790	0·06230
	Inoculated		
	5	1·5615	0·07285
	6	1·4406	0·07980

In the second experiment, seedlings of Spratt Archer barley were used. The seedlings were prepared in the way described above; fifty plants were dried for analysis when the experiment was begun. Two samples of 225 plants each were placed with their cut ends in modified Crone's nitrogen-free solution. One sample was kept rust free, the other was infected with *Puccinia anomala* race 12. Fifty seedlings were taken every three days from each sample and dried at once. After twelve days the experiment was discontinued and the samples analysed. The results of the analyses are given below:

		Dry weight in gm.	Absolute nitrogen in gm.
	Initial control	0·7206	0·03012
	Rust-free		
No. of days the seedlings were kept in the solution	3	0·8853	0·0326
	6	0·9908	0·03073
	9	1·0067	0·0326
	12	1·8007	0·02996
	Inoculated		
No. of days the seedlings were kept in the solution	3	0·9156	0·033015
	6	1·1150	0·03458
	9	0·9922	0·03542
	12	0·8836	0·04809

The results of other experiments not given here agree in essentials with those quoted above, although in some experiments with *P. glumarum* the apparent increase in nitrogen content was not so marked. Irregular results were found with other rusts, particularly if the leaves remained wilted for long periods after inoculation. Nevertheless the experiments point to an increase in the amount of nitrogen in the rust-infected plants.

I realize the difficulties involved in demonstrating nitrogen fixation by an obligate parasite, yet I feel that the above results are sufficiently suggestive to warrant their being brought to the notice of other workers.

Nomenclature of Nudibranchiate Mollusca

WANTON changes in the nomenclature of animals are so injurious to zoology by confusing its literature, and so heavily handicap the study of systematic problems, that I seek the publicity of NATURE for the exposure of a particularly flagrant case. This is the synonymic List of British Nudibranchiate Mollusca by Iredale and O'Donoghue[1], the nomenclature of which was adopted in the last edition of the "Plymouth Marine Fauna" of the Marine Biological Association (1931). My attention was directed to it by noticing that some extraordinary names for these animals were being used by recent workers at Plymouth, who naturally followed the guidance of the Association's official "Fauna".

The revolutionary nature of the scheme may be seen from the fact that in it familiar names like *Doris*, *Triopa*, *Tritonia* and *Doto* have completely disappeared, and that no less than 40 out of the 71 species recorded bear names different from those in Alder and Hancock's "Monograph", as revised for the Ray Society by the late Sir Charles Eliot in 1910. No reasons were given in the "Fauna" for the rejection of Eliot's nomenclature, and no opinion was expressed as to the validity of the new scheme. As an old student of the group, familiar with the careful workmanship both of Alder and Hancock and of Eliot, I have thought it desirable to subject Iredale and O'Donoghue's paper to a critical examination, and submit herewith a few examples of their treatment.

(1) *Doris* (*Archidoris*) *tuberculata*, Cuvier, 1804.—Our largest and most familiar species of *Doris* has been known exclusively by this name for nearly a century. Iredale and O'Donoghue assert, but without evidence, that it is not Cuvier's species. Their statement traverses the unanimous testimony of Alder and Hancock, Bergh, Eliot, Fischer, Cuénot and Vayssière, in fact of every expert investigator. Their change of its name to *A. britannica* (Johnston, 1838) is baseless.

(2) *Doris* (*Jorunna*) *johnstoni*, A. and H., is another well-known species which has been universally known under this name since Alder and Hancock first accurately defined it in their monograph. Iredale and O'Donoghue change the specific name to *tomentosa*, Cuvier, 1804, on the ground that Fischer (1869, 1870) "pointed out this synonymy" and that Cuénot (1903) "confirmed" it. The facts are that Fischer claimed that *tomentosa*, Cuvier, was distinct from *johnstoni*, while Cuénot said that the synonymy of *johnstoni* with *tomentosa* was at most a "possibility" which could not be established, since Cuvier's description was "*absolument insuffisante*"! Fischer had made a superficial examination of some specimens labelled *D. tomentosa*, Cuv., in the Paris Museum, but the single authentic type was not among them.

Moreover, Iredale and O'Donoghue omit the fact that Bergh conclusively identified as *D. johnstoni* some specimens in the Leyden Museum which Cuvier himself had authenticated as *D. stellata*, Gmel. (Bergh, *Verh. z. b. Ges. Wien*, 1893)—a species of antiquarian interest only, but from which Cuvier had expressly distinguished his own *tomentosa*. Thus, if we assume that *tomentosa* really was identical with *johnstoni*, Cuvier could not recognize his own species when it was before him. Enough has been said to show that the only indisputable name for Alder and Hancock's species remains *Doris* (*Jorunna*) *johnstoni* A. and H.

(3) *Doris verrucosa*, Linn. (Cuv.). This, the type-species of the Linnean genus *Doris*, had remained unrecognized until Cuvier's "Mémoire sur le genre Doris" (1804). Iredale and O'Donoghue dismiss Cuvier's identification with the assertion that Linnæus's species was "based on a specimen described by Rumph and figured by Séba, which is indeterminable", thus begging an important question and brushing aside essential facts. It is generally admitted that Linnæus's first attempt, in the tenth edition of the "Systema" (1758), to define the sea-slug *Doris* was both erroneous and confused. Cuvier pointed out that Linnæus's citations from Rumph and Séba indicated an "Oscabrion", that is, a Chitonid (Séba's plate suggests a *Cryptochiton* with reflected mantle), but the generic diagnosis included statements about appendages of which there was no indication either in Rumph or Séba ("*Tentacula ad os circiter octo*"). This suggested to Cuvier that, in addition to Séba's figure, Linnæus had a true *Doris* before him, though wrongly orientated, and Bergh, long afterwards, reached the same conclusion. Anyhow, after Bohadsch had cleared up the anatomical errors (1761), Linnæus corrected his diagnosis in the twelfth edition, changed *os* to *anum*, distinguished the true tentacles as "retractile within foramina", and nevertheless retained *verrucosa*, along with three new species of indubitable *Doris*, as members of the revised genus. Cuvier had found some specimens in the old "Cabinet d'Histoire Naturelle" which in fact combined the verrucosity of Séba's figure with the revised generic characters. He accordingly claimed the species, which he described and figured, as in all probability Linnæus's hitherto unrecognized type, and it has since happily proved to be the commonest Mediterranean species.

Cuvier's identification was in every sense legitimate and has been admitted without exception by every subsequent investigator. It was tantamount to a fixation of the type for all time. Accordingly the old genus *Doris* stands, in spite of its original ambiguity, and includes five British species at least, as detailed in Eliot's Revision.

These few examples, out of many similar, show that Iredale and O'Donoghue draw no distinction between proved conclusions and mere opinions. Until the changes of nomenclature introduced by them have been confirmed independently, I would advise serious investigators to record their discoveries under the more stable and historic names of Eliot's authorized Revision.

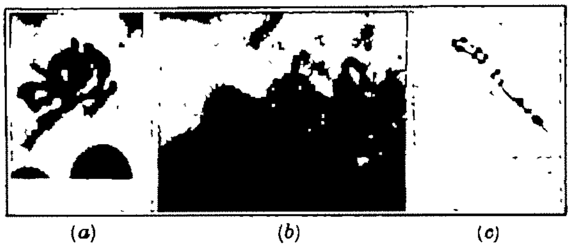
Chromosome Structure as Observed in Root Tips

THERE are some features of the structure of the somatic chromosome which can be observed without any special technique. These are the primary and the secondary constrictions (the last including the SAT- and the NO-SAT-constrictions) and also the heterochromatin and the euchromatin.

Recently, Darlington and La Cour[1], by means of a special technique, have observed a "new differentiation" in the chromosome which appears as a decrease in its thickness owing, they suggest, to these parts of the chromosome "being coiled in a finer thread of smaller diameter than the rest of the thread".



METAPHASES OF ROOT TIPS OF *Trillium ovatum*, PURSH; (c) IS AN ENLARGEMENT OF THE PART BETWEEN THE ARROWS IN (b).

The connexion of the satellites to the chromosomes has been referred to in the literature as 'SAT-thread', although in some cases (Heitz[2] and Resende[3]) this connexion appears more as a band than as a thread. From the comparison of my figure[3] of a SAT-band in *Dioon spinulosum* with the photographs of Darlington and La Cour of *Paris polyphilla*, one can see that there is no difference at all between them. As these authors did not observe the nucleoli, however, it is very likely that they failed to recognize such differentiations as SAT-constrictions. Similar aspects were observed by me in the proximal satellites of *Trillium ovatum* (see *a*) and other plants[4]. In all these cases, as in *Dioon*, the nucleoli have been observed and there can be no doubt that we were dealing with true SAT-differentiations.

In a metaphase preparation of *Trillium ovatum*, in which this SAT-band was particularly extended, one could clearly see that this zone is deprived of kalymma and that the chromonemata there showed a differentiation identical with that observed hitherto only in meiosis (cf. Belling[5]). Exactly as Belling[5] observed in a pachynema of *Lilium pardalinum*, I found in somatic metaphases (root tips) of *Trillium ovatum* (see *b*) groups of four chromomeres linked together by fine (?) fibrils. The observation of such a differentiation in mitosis shows the identity of the somatic chromonemata with those of meiosis.

The present observations are a confirmation of the hypothesis put forward by Heitz[6] on the constitution of the chromosome, but, of course, only with regard to the number of the chromonemata. It is now demonstrated that the chromonema is split longitudinally, as suggested before by several authors (cf. Geitler[7] and Straub[8]). The facts referred to also show that the longitudinal splitting of the chromonema is already present at metaphase.

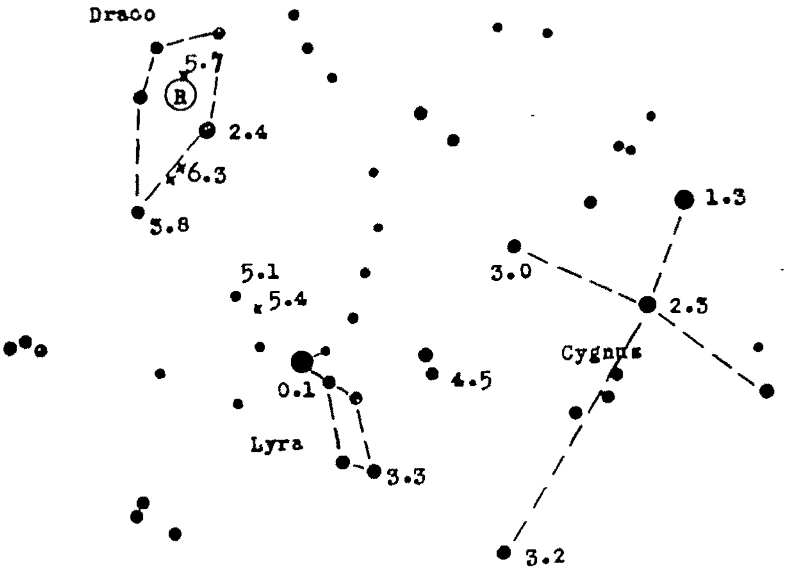
Giacobinid Meteors in 1939 and 1940?

ON October 9, 1938, when the earth passed through the region occupied eighty days earlier by the faint, short-period comet Giacobini-Zinner, the strongest meteor shower of the century appeared for a few hours. The best available orbit for the comet indicates that it will again pass near the earth's orbit on February 23, 1940; thus in 1939 the earth will precede the comet to the nodal point by 136 days and in 1940 follow it by 229 days. It therefore appears probable that some recurrence of the shower, but of a quite unpredictable intensity, may be anticipated on October 9 or 10 in either or both of these years[1]. Observations from widely separated localities are of great value in the investigation of the internal structure of meteoric swarms, hence a request is made for reports from anyone detecting the shower. The radiant will be in the head of the constellation Draco, north and west of the bright star Vega. In 1939 the moon, aged twenty-five days, will not interfere; but in 1940, aged eight days, it will illuminate the evening sky.



Continued investigation of the Giacobinid system, in which both meteor showers and the comet may be observed, should greatly increase our knowledge of the structure of comets and the process by which they disintegrate into meteor swarms. In the study of the structure of meteor swarms, certain types of data are of especial importance and unless they are obtained and recorded with the more general observations of a meteor shower, the studies are likely to be of little value. For this reason the following observing programme is suggested for a single observer assisted by a recorder. If additional observers are available, the several types of observation may be delegated.

(1) Determine as closely as possible the position and size of the radiant area, and, if possible, fix the position of the radiant area when it is at several appreciably different zenith distances.

(2) Have each observer record the magnitude, or identity, of the faintest star that he can see. If the transparency changes appreciably during the observations, record the stellar limit frequently.

(3) Choose some specific region of the sky, for example, the polar region, or the zenith, and count

the number of meteors seen during intervals of five minutes.

(4) At least once each hour count, over intervals of not less than five minutes, the number of meteors of each magnitude. A continuous record of the magnitudes of all meteors seen, from which any time-variations of the magnitude distribution may be found, would be extremely valuable.

(5) If low-power binoculars or a comet-seeker are available, determine and record the number of meteors of various magnitudes seen through such optical instruments.

(6) Utilize whatever photographic equipment is available for securing both trails and spectra of the meteors. For detailed suggestions see papers by Dr. P. M. Millman[2].

(7) When reporting the observations, give all the data that are obtained and descriptions of the field of view, time system, telescopes, etc., employed. At a later date superfluous information may be disregarded, but omitted data cannot be recreated.

For convenience in identifying the radiant, its approximate position is indicated by R in the accompanying chart. The location and visual magnitudes of a few easily identified, faint stars are also indicated (crosses) to aid in fixing the limit of visibility and in determining the magnitudes of faint meteors.

Points from Foregoing Letters

J. F. Allen and J. Reekie state that the force associated with heat flow in He II has been found to possess two components. When heat flows in a tube containing He II, the liquid which is close to the surface of the capillary is forced to flow in the direction opposite to that of the flow of heat. This is the so-called fountain effect. In the centre of the capillary, however, liquid is forced by the flow of heat to move in the same direction as the heat flow. There is evidence that the fountain effect, that is the surface component, becomes saturated when the heat current is sufficiently high.

According to C. Møller and L. Rosenfeld, recent developments of the vector meson theory lead to the view that the meson field is neutral. They state that the quadruple moment of the deuteron, and indeed the consistency of the whole meson theory of nuclear forces, is much clarified by introducing pseudoscalar meson fields as well as the vector fields.

G. W. Brindley and G. H. Atkinson point out that the characteristic temperature of copper obtained from X-ray measurements at low temperatures agrees with the specific heat value, in contradiction to the previously reported result of Owen and Williams obtained from X-ray measurements at high temperatures.

E. A. Owen and R. Wilson Williams find that the characteristic temperature of gold deduced from X-ray measurements agrees with the value obtained by other methods. They suggest that the results which they previously recorded for copper at high temperatures need further investigation under more rigorous conditions.

H. Benioff and B. Gutenberg describe results obtained with electromagnetic microbarographs designed by the former. They respond to the range of frequencies 5 cycles per sec. and to 2 cycles per minute, and are capable of recording the natural movements of the atmosphere. Wave movements, produced by earthquakes, surf or artificial sources, and also air currents can be detected.

The lethal effects of neutrons and γ-rays on broad bean roots are compared by L. H. Gray, J. Read and J. C. Mottram. Using earlier results, it was found that the biological effect produced by a given amount of absorbed γ-ray energy was produced by about one tenth of this amount of absorbed neutron energy.

A. R. Martin and R. N. Hermann find that when a quantity of copper salt equivalent to the sodium oleate present is added to an emulsion of benzene in water, the solid obtained on evaporating the benzene thrown out is different from the product of the interaction of sodium oleate and copper salts in aqueous solution. They make suggestions about the nature of the double layer round the oil droplets in emulsions.

B. Mendel, D. Mundell and F. Strelitz find that calcium and magnesium ions activate and potassium ions inhibit cholinesterase. These effects are brought about by physiological concentrations of the electrolytes and become more pronounced the lower the concentration of acetylcholine.

B. d'Oliveira describes some experiments in which it is shown that the leaves of cereal seedlings experimentally inoculated with some rusts (Puccinia) present an increase of the total amount of nitrogen. The question is put whether rusts are able to fix nitrogen directly from the air.

W. Garstang criticizes the nomenclature of British Nudibranchiate Mollusca which was adopted in the last edition (1931) of the "Plymouth Marine Fauna" of the Marine Biological Association from Iredale and O'Donoghue's Synonymic List of 1923. He gives examples of the unreliability of this list, and advises a return to the nomenclature of Eliot's Revision of Alder and Hancock's Monograph (Ray Society, 1910).

F. Resende submits photomicrographs which he claims support the view that the chromonema is split longitudinally at metaphase.

The possibilities that meteor showers, associated with comet Giacobini-Zinner, will appear on October 9–10, 1939 and 1940 are discussed by F. Watson, and the most valuable types of observations are detailed.

RESEARCH ITEMS

Early Copper

EXPERIMENTS in smelting copper from ores have been carried out by H. H. Coghlan with the view of throwing light on the supposed accidental discovery of copper smelting by primitive man (*Man*, July 1939). Primitive conditions were simulated so far as possible, to show whether copper could be produced in a 'hole in the ground' or camp fire. The green carbonate malachite was selected as the most probable material from which the earliest smelted copper was produced. A cone of charcoal was built up in a hole in the ground about three feet in diameter, and surrounded by a ring of stones. The ore was well embedded in the centre of the cone. A bright red heat was obtained, which could not have been increased without a forced draught. The fire was kept at full heat for some hours, and then allowed to die down slowly. The malachite had only been reduced to black oxide of copper, and no metallic copper was produced. Failure is attributed to excess of air, and later experiments proved that low temperature was not the cause of failure. The theory of accidental discovery precludes the use of bellows to produce a forced draught, as this is a method which belongs to a sophisticated copper-smelting technique. An alternative theory is put forward that accidental discovery may have resulted from the employment of a pottery kiln, especially in view of the fact that the use of pottery preceded the discovery of copper. A test was made in a simple kiln, such as that which had been in use at Ereed in the Alt Valley, where the baking chamber was simply a dome of brick or burnt clay. The kiln following this model was covered with charcoal, and the fire kept at a good red heat for some hours. Metallic copper was produced, at first as sponge copper, and afterwards with a closer packing, as a compact and close-grained bead. The malachite may have been introduced into the primitive pottery kiln by accident or in the form of a paint or slip, or made up as a glaze.

Tree Ritual in Southern Rhodesia

A NUMBER of examples of tree ritual among the Bantu tribes of Southern Rhodesia have been collected by F. Posselt (*Man*, August, 1939). In the Marandellas District, Central Mashonaland, a tree on a ridge, a prominent landmark, was known to the natives as "the tree without a name", so-called because it was the only one of its kind. Before British occupation in 1890, religious rites were performed around it, particularly by the Barozwi. The assembly danced around it and made offerings of black cloth and beads. The tree was believed to be the abode of a great tribal spirit; and the rites were intended to propitiate, and ensure the prosperity of the community, as well as a bountiful season. The sacred grove of the *miti michena*, "the white trees", was the scene of a ritual murder of human sacrifice in 1923. This grove, in the Darwin District, Northern Mashonaland, is the centre of the Karuwa cult of the Rainmaker, whose wife was obliged to live within the enclosure to which no male, except the officiating priest, was admitted. Contact with any male defiled the spirit's wife and was regarded as a rape, with the result that the angered spirit visited the land with a prolonged drought, refusing to be reconciled until the offending male had been immolated. The chief's son in the instance mentioned was burnt to break the drought which had followed his trespass. Among the Vazezuru and the Kalanga, offerings of beer and porridge are made to the ancestors under a large tree. Among the Amandebele and others, the use of any timber or fuel of the *citamuzi*, the "tree of discord", is forbidden. It is used at funerals as a symbol of farewell greeting.

Mollusca of the John Murray Expedition

Two recent monographs deal with the Opisthobranchs and Pteropods ("A Systematic and Anatomical Account of the Opisthobranchia" by N. B. Eales, British Museum (Natural History). The John Murray Expedition 1933–34 Scientific Reports, 5, No. 4. Pteropoda by H. G. Stubbings, 5, No. 2; 1938). Dr. Eales's work on the Opisthobranchs is most excellent and is a valuable addition to our knowledge of the group, although the specimens available are somewhat scrappy and possibly not altogether representative of the region. She has studied specially the nervous and reproductive systems with the alimentary system in less detail. This will go far in elucidating the relationships of the various genera, especially so because they are illustrated with very carefully drawn figures. Notes on the feeding of two species, *Hydatina* (*Aplustrum*) *velum* and *Hexabranchus sanguineus*, are interesting. In the Hydatina the alimentary canal is remarkably long and the thin-walled crop fills the greater part of the body cavity. In the crop was found a cirratulid worm, 80 mm. long and 4 mm. wide, more than four times as long as the Hydatina itself. Bergh noted a similar worm in this species which must select its food. In *Hexabranchus sanguineus* the crop was full of Foraminifera, worm tubes and pieces of gastropods and echinoderms which fully account for the very much worn radula. A comparison of the chief types represented provides a series exhibiting progressive concentration of the nervous system, the least specialized being *Bulla ampulla*, the most specialized *Hexabranchus sanguineus*. The collection of Pteropods is small. All are known forms and none occur in large numbers. Mr. Stubbings has attempted to show the vertical distribution of certain species and his notes are interesting and suggestive.

Hawaiian Bivalves

THE recent work by William Healy Dall, Paul Bartsch and Harald Alfred Rehder entitled "A Manual of the Recent and Fossil Marine Pelecypod Mollusks of the Hawaiian Islands" (*Bull. Bernice P. Bishop Museum*, 153; 1938) is a comprehensive account of Hawaiian Pelecypoda, including a very large number of species. It is purely conchological, dealing only with the shells and not the animals, but will be indispensable as a work of reference. The main part is based on the valuable collection of Mr. D. Thaanum presented to the United States National Museum, but added to this are specimens from collections, chiefly from deeper waters, made by the U.S. Bureau of Fisheries steamer *Albatross* in Hawaiian waters, and smaller collections made by individual workers.

Paul Bartsch, in his introduction, is inclined to attribute the Pelecypod fauna of the Hawaiian Islands mainly to drift. The fauna is composed, with few exceptions, "of just such species and such only, as might use this type of transportation". The work is illustrated by fifty-eight good photographic plates.

Powdery Mildew of the Rose

THE fungus *Sphaerotheca pannosa* var. *rosae* causes the powdery mildew disease of roses, and is the most serious parasite of this national flower. Control of the malady, however, has often been difficult, owing to lack of exact knowledge of the factors which affect the development and distribution of the disease. Karla Longrée has recently investigated this question (Cornell Univ. Agr. Exp. Sta. Memoir 223, Ithaca, N.Y., U.S.A., April 1939). The effect of external conditions upon the propagation of the fungus appears sufficiently limited to account for the sporadic nature of the malady. Optimum temperatures for spore germination, for example, fall rapidly from 27·5° to 21° C. during the first few days after liberation. Sporulation only takes place between 9° and 27·5° C., and spores quickly lose their viability. Relative humidity of the atmosphere, however, provides an even greater obstacle to spore germination, which was only good between the narrow limits of 97 and 99 per cent humidity. Young rose leaves, however, appear to have a layer of air with such a high relative humidity, close to the surface, particularly on the underside, and so are prone to attack by the fungus. Many other details of the effect of climatic environment upon the fungus are given in the paper, which should provide a valuable basis for the more efficient control of the malady.

The Daruma Volcano, Japan

HISASHI KUNO has recently made a study of this volcano (*Bull. Earthq. Res. Inst., Tokyo*, 16 (4), 763–771 ; 1938) and finds that it may best be classed as a shield volcano of the Hawaiian type similar to the Prospect Peak and Mount Harkness volcanoes of the Lassen Volcanic National Park as have been described by Howel Williams. It has a breached central crater and a gently sloping flank, having been built up chiefly by repeated gentle outpourings of lavas with scarcely any violent explosive eruption. Each lava was accompanied by large blocks formed by the breaking down of the already consolidated scoriaceous crusts. The composition of these lavas did not change much from one effusion to another, being mostly hypersthene-augite-andesite, becoming only slightly richer in olivine towards the later stage of activity. Augite-olivine-basaltic andesite and olivine-basalt were also erupted occasionally during the later stage. A comparison of the extent to which the volcano has been dissected, with that of the other north Izu volcanoes, suggests that it is of older Pleistocene age or slightly older, though no decisive conclusion can be drawn.

The Atomic Weight of Hydrogen

ON the basis of a protium-deuterium (H/D) ratio in normal water of 5000, the International Committee on Atomic Weights in 1938 changed the accepted atomic weight of hydrogen from 1·0078 to 1·0081. No reference to the source of this ratio was given and the higher ratios 6900 and 6500 found by Gabbard and Dole and by Hall and Jones respectively, were not mentioned. J. A. Swartout and M. Dole (*J. Amer. Chem. Soc.*, 61, 2025 ; 1939) have confirmed the ratio 6900 by a new exchange reaction $H_2+HOD \rightleftharpoons HD+HOH$ and also reinvestigated the density of water made from atmospheric oxygen as compared with normal water, as the published data vary from 6·0 to 8·6 parts per million excess density as compared with normal water. Lake Michigan water was used and water made from the oxygen of this water and pure protium had a density 15·5 p.p.m. smaller than normal Lake Michigan water, giving a ratio H/D = 6970. Water containing normal Atlantic Ocean oxygen and pure protium was 15·7 p.p.m. lighter than normal Atlantic Ocean water, giving a ratio H/D = 6900. Deuterium-free hydrogen was burned with atmospheric oxygen and the density of the water produced compared with that of water containing normal Lake Michigan oxygen and pure protium, and the atmospheric oxygen water was 6·6 p.p.m. heavier, which corresponds with a greater atomic weight of oxygen in air of 0·000119 ± 0·00002 atomic weight units. The chemical atomic weight of hydrogen calculated from the new H/D ratio is found to be 1·0080 instead of the value of 1·0081 recently adopted by the International Committee.

Fluctuation Voltages

IT has been known for a long time that there is a spontaneous oscillating potential difference between the ends of an isolated resistance. This is generally attributed to thermal agitation of the free electrons. It is known to have an effective value which is proportional to the resistance and to its absolute temperature. In a paper by F. C. Williams (*J. Inst. Elec. Eng.*, Aug.), various methods are given of representing the voltage, current, etc., of the thermal fluctuations both in simple and in complex networks. The oscillations are augmented if the resistance, whether an open or a closed circuit, carries a current which has passed through a thermionic valve. The two components of oscillation are called thermal and thermionic fluctuation voltages respectively. All electrical communications suffer from them, as they always form an inevitable background which ruins intelligibility when the strength of the signal is less than some definite amount, which is independent of subsequent amplification and magnifies both alike. It is important to be able to predict the fluctuation voltage inherent in any assembly of circuits and thermionic valves. Although there has been considerable research in this direction the exact mechanism of these effects has not yet been discovered, and it is very laborious to estimate their probable magnitude in complex circuits. The author recently described a method of representing the phenomena which enables the fluctuation generated in any specified network to be computed by the ordinary processes of circuit analysis, by ignoring the physical mechanism which produces the effects. The author states that extensive experiments have completely vindicated this method of representation. In this representation the distribution of potential developed along the length of a resistance is simulated, for simplicity, by a concentrated generator producing a specified E.M.F. and supposed inseparable from the resistance ; an analogous representation is adopted for thermionic fluctuations. This method, which is useful in technological applications, is called 'voltage representation'. An alternative method, which is termed 'current representation', is sometimes more convenient. Both methods are described in this paper.

HEALTH AND SAFETY IN INDUSTRY

THE annual report of the Chief Inspector of Factories for 1938 gives an encouraging picture of the way in which health and safety in industry in Great Britain are being improved. Although the report deals only with the first six months during which the Factory Act of 1937 was in force, it indicates that great progress has been made in applying the new code and raising the standard of all factories and workshops to the level of the best. Indeed, a striking feature of the coming into operation of the Act, the report points out, has been the co-operation of employers, whose inquiries have been directed to the best manner of doing this or that, rather than to the necessity of doing it. Accordingly, the factory inspector is now regarded more as an expert adviser on problems of health and safety and less as an official with punitive powers.

In regard to safety, the new Act marked an extension of safety regulations to diminish accidents. The report shows that in 1938 the number of reportable accidents was 7 per cent less than in 1937, while fatal accidents were reduced by 6 per cent. While, however, these figures remain at the high level of 180, 103 and 944 respectively, there is still plenty of room for improvement in this respect, and the fall in accidents must be attributed to some extent to the reduction of the number of people in employment in consequence of the trade depression. In this connexion, the chief inspector pointed out that the decrease was especially marked among the fatal accidents on factory premises, and considered that the new safety requirements are already beginning to take effect. It should, of course, be remembered that the relative value of the accident figures for 1938 is affected by the wider requirements in the new Act for reporting accidents.

An important factor in the prevention of accidents is the work of the Safety Committees and safety officers throughout the country, particularly in the larger factories. In such work, scientific workers have an important part to play. Success in this matter depends largely on their technical knowledge and interest, and their skill in enlisting the co-operation of fellow-workers who may not possess such expert knowledge. Moreover, significantly enough, the report points out, special difficulty is often experienced in small factories, for example, in the elimination of fire risk through effective protection of circuits from persistent earth leakage, because neither the instruments required nor the ability to use them are available.

If, therefore, the report contains welcome evidence that the management side is increasingly alive to its responsibilities in this matter, it once more endorses the far-sightedness of the policy of such professional associations as the British Association of Chemists in attempting to secure that certain specified operations are carried out under the direct supervision of properly qualified persons. This is indeed essential in the development of new processes, and the value of such a safeguard tends to increase as the pressure due to national defence requirements increases. From the point of view of safety, no less than health, the reduction of hours of work is a wise and beneficial measure.

Once again an important section of the report is concerned with accidents to young workers. A most serious problem in factories to-day is indeed to protect young workers from the alarming proportion of accidents occurring in the age group 14–18, which are often due to carelessless, ignorance or lack of discipline. The education authorities are now endeavouring to prepare boys and girls for the risks of their future employment by giving such training as they can to the young people while they are still attending colleges or schools. Progress in this matter obviously depends on close co-operation with employers themselves. The report points out that the firms which are most successful in reducing accidents to young workers are those which regard their employees both from the personal point of view and that of their future value as skilled workers. Moreover, if the number of accidents is to be reduced as far as possible, the training and supervision of the young entrants into industry must be extended beyond their instruction with regard to the use of machinery, for most of the injuries due to accidents come from other causes.

At the present time there is a further factor in the shortage of young workers, which may tend to increase this already alarming incidence of accidents among young workers. Due to this shortage there may be greater danger that boys and girls may be placed in positions for which they are not most suitable. If it is a counsel of perfection at the present time to select boys and girls who are the most suitable mentally and physically for the work which has to be done, at least greater care could be taken to prevent those specially prone to accidents from being placed in the more hazardous posts. Moreover, the fact that accidents tend to occur to particular boys and girls whom the management consider to be among the smartest and most intelligent in the works is a further demonstration of the need of close guidance and supervision if only to maintain discipline, to remedy lack of experience, for example, as to the type of clothing worn, and prevent dangerous experiments on the part of young workers due to their inquisitiveness and eagerness to try out ideas of their own.

While, therefore, the evidence presented in this report shows that the great developments in organized attempts to reduce accidents in recent years are gradually achieving their object, there can be no reasonable room for doubt that great efforts still continue to be required in this field, and notably in attention to the young workers. The field of research open to the Industrial Health Research Board remains a wide one, and it is significant that special attention is directed to this matter in the programme recently formulated by the Scientific Advisory Committee of the Trades Union Congress. At its first meeting this committee agreed that the subjects upon which the committee might be consulted in regard to their effect on labour and social conditions should include the position of research in relation to industrial and occupational diseases with a view to prevention rather than cure, and also researches into industrial fatigue and nerve strain, including systems of labour measurement in relation to shorter working hours, holidays and minimum periods for rest and recreation. Two sub-committees have been formed to give their attention to these subjects and a third sub-committee to deal with the effects of new industries, new materials, new uses of new processes, upon the distribution, displacement and character of labour with particular reference to plastics, textiles and non-textile products.

In view of the increasing responsibilities which scientific workers must assume for control and management in industry, the report of the Chief Inspector of Factories is a timely reminder to them of their opportunities and responsibilities in this important field.

FISHERY RESEARCH IN SCOTLAND

THE passing of the Fishery Board for Scotland, under the Reorganisation of Offices (Scotland) Act, means the removal of a landmark from the field of fishery research. As the Development Commissioners observe in their latest annual report, the Board was the first department of Government in the United Kingdom to possess a permanent scientific organization, and its scientific staff was responsible for many of the earlier classical discoveries in marine research, while in more recent years it has made important contributions to the development of fishery science.

Since its inception, the Board has had its headquarters in Edinburgh, one of the homes of the modern science of oceanography. From Edinburgh, Edward Forbes conducted much of his pioneer work of shallow-water dredging and Dr. Bruce his polar researches, and the city is for ever to be associated with the famous *Challenger* expedition and the names of those deep-sea explorers, Sir Wyville Thomson and Sir John Murray. The last-named was scientific member of the Fishery Board and the chief British delegate at the International Congress held at Stockholm in 1899—a congress which led to the formation of the International Council for the Exploration of the Sea.

It would probably amaze some of these pioneer fishery investigators to see how far governmental interest in research, land and marine, has progressed since their time. There are many to-day who, like Forbes, would prefer to see scientific research conducted without the trammels of officialdom; but finance is a hard taskmaster and has a way of assuming the direction and control of policy. Certainly, without Government funds the conduct of marine research would, in view of the costly equipment and staff required, be a difficult undertaking for private enterprise.

It was in 1882, following a report by a Select Committee of the House of Commons, which was impressed by the progress of fishery research in the United States, that the Fishery Board for Scotland was empowered to carry on scientific researches. The funds provided were on a modest scale, but the Board was enabled in 1886 to acquire a small steam research vessel, the *Garland*, which was employed mainly in investigating the effects of trawling on the inshore fisheries. With the great development of trawling, this question had become one of much public and political interest, especially in Scotland, where the inshore fisheries are of considerable importance. The investigations are described in Prof. W. C. McIntosh's "Resources of the Sea", in which the author did not support the Board in the policy of restriction of trawling on which it decided.

In 1895 the Board was reconstituted, and "a person of skill in the branches of science concerned with the habits and food of fishes" was thenceforward included as one of its members. The role was filled in turn by such distinguished men of science as Prof. Cossar Ewart, Prof. W. C. McIntosh and Sir John Murray, and since 1898 the scientific member of the Board has been Sir D'Arcy W. Thompson, who has taken so long and honourable a part not only in fishery science but also in many other fields of culture and education.

The establishment in 1902 of the International Council for the Exploration of the Sea gave a great fillip to marine research, and the share of the programme of international research assigned to Great Britain was entrusted, so far as the northern half of the North Sea was concerned, to the Fishery Board for Scotland acting as agent for the Treasury. The work in the southern half of the North Sea was undertaken originally by the Marine Biological Association and afterwards, in 1910, by the Board (now Ministry) of Agriculture and Fisheries.

A new research vessel, the *Goldseeker*, was provided for the Fishery Board in 1902, and she was replaced in 1920, by means of a grant from the Development Fund, by the research vessel *Explorer*, which is still in commission.

Laboratories were set up at Dunbar, Granton and Tarbert (Loch Fyne) and finally at Aberdeen, where the Board's scientific staff is now stationed. The Board has been fortunate in securing the services of a succession of scientific superintendents of outstanding ability, of whom Fulton and Bowman may be specially mentioned. Apart from his varied contributions to fishery science, Fulton found time to write the "Sovereignty of the Sea", a valuable historical survey of questions of maritime jurisdiction, while Bowman laid the foundation for the forecasts which have now become possible of the stocks of haddock in the sea.

The statistical records of the Board are of the greatest value. Sir D'Arcy Thompson is personally responsible for a series of statistical reports on the fisheries of the North Sea, which are indispensable to any proper study and appreciation of fishery problems.

In conclusion, it is fitting to mention the contributions made by the Board to salmon and freshwater fishery research. The names of Archer, Young, Calderwood and Menzies, in turn inspectors of salmon fisheries, stand high as authorities in this branch of science.

SCIENCE NEWS A CENTURY AGO

Propagation of Heat in Liquids

ON September 14, 1839, the *Athenæum* said: "The experiment of M. Despretz concerning the propagation of heat in liquids has been attended with the most satisfactory results. From these it appears that a liquid column being heated at the upper part, the heat is propagated according to the same laws as those belonging to solid bodies; that the temperature decreases from the axis to the surface, and from the surface to the wall of the side. The depth to which solar heat penetrates in a given time may be easily calculated by these data in large lakes and isolated seas". The French physicist César Mansuète Despretz, well-known for his studies of heat, was born in 1792 and died on March 15, 1863.

Scientific Gossip

ON the same page in the *Athenæum* as the above note appeared, was a column of 'Weekly Gossip' in which it was said: "The prevailing quiet at home has induced us to hunt over the foreign papers and journals, in the hope that something might be thence gleaned, but all seem subject to the same summer influences. It may be well, however, to remind our scientific friends that . . . the Italian savants are to assemble at Pisa in October; that the French Geologists meet in the same month; and that the German Naturalists meet this year at Pyrmont. An account appears in the *Nördische Blätter* of an immense landslip at Federowka, a village situated on the Volga . . . The motion of the ground continued with more or less violence, for nearly three days, and seventy houses were either wholly or partially destroyed. . . . On one side of the village rise high hills, the upper strata of which are of limestone, but the lower of various kinds of clay, while on the opposite side it is washed by the Volga, which is here hemmed into a narrow bed; and the waters thus confined are supposed to have forced a passage between the stony and alluvial beds.

Proposed Society for Practical Mechanics and Chemistry

THE *Mechanic and Chemist* of September 14, 1839, published a note from "Tyro Chemicus" saying: "The increasing desire which the middle classes evince for information in every department of science, particularly those branches in which mechanics and chemistry form a part, shows the immediate necessity of all students in the above branches of science combining together and forming themselves into a society in which practical mechanics and chemistry are exclusively studied, and affording them benefits which the Mechanics' Institution and other similar institutions have denied them; for although they may be called mechanics' institutions, etc., yet no person will attempt to deny that practical mechanics is in most of them totally excluded. . . ." The same remark applied to practical chemistry, and the Editor of the *Mechanic and Chemist* in recommending the proposal said: "Another important advantage derived from a society of this description is the reciprocal instruction resulting from the intercourse of the numbers. Many difficulties may arise to a practical man which would sooner and more satisfactorily be disposed of by a jury of workmen, than by all the erudition of the Royal Society".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

AGRICULTURAL CHEMIST at the School of Agriculture, Houghall, Durham—The Director of Agriculture, 23 Old Elvet, Durham (September 14).

TEACHER OF MINING SUBJECTS in the Whitwood Mining and Technical Institute—The Secretary to the Managers, Education Offices, Castleford, Yorks (September 15).

RESEARCH ASSISTANT IN PHYSICS—The Registrar, University, Leeds 2 (September 20).

PROFESSOR OF CHEMISTRY—The Registrar, Indian Institute of Science, Bangalore, India (October 31).

PROFESSOR OF BIOCHEMISTRY—The Registrar, Indian Institute of Science, Bangalore, India—(October 31).

ASSISTANT for the Department of the Advisory Economist—The Secretary and Bursar, Seale-Hayne Agricultural College, Newton Abbot, Devon.

THE FUTURE OF CIVILIZATION

THE supreme need for concentrating national effort upon the successful prosecution of the war, and securing the overthrow of the forces which threaten good faith and understanding among the nations, should not be allowed to blind us to the necessity of preparing the foundations upon which a just and enduring peace can be based. It is, indeed, to defend the moral and spiritual realities upon which civilization itself depends that we have been driven to enter this conflict. To keep those moral issues clearly defined is essential if we are to sustain the sacrifices and effort which the task to which we have addressed ourselves will demand. We should not forget that it is possible to win a war and lose the peace.

There is, indeed, no reason for those who recognize that the future of civilization depends upon effective co-operation between governments and nations either to be dismayed even at the present moment or to relax their efforts to achieve co-operation. They must, indeed, seek rather to be ready to seize the opportunity for constructive statesmanship, when it has been won from the aggressor and respect for the rights of others re-established. Apart from the moral issues upon which the conflict has been joined there is, indeed, welcome evidence to be found of the success of efforts in this direction in certain fields.

Among such evidence may be cited the encouraging report of the special committee which was recently appointed by the Council of the League of Nations to consider how best international co-operation could be developed in economic and social affairs. The pre-occupation of public interest with the League's efforts to abolish war, and disappointment over its failure to create an effective system of collective security, have led to failure to appreciate its success in other directions. Even those who are aware that most of the League's activity has been concerned with social and economic problems have little idea of the varied character of this activity, and how beneficial have been its results.

The report of this special committee should redress the balance. The progress of civilization is dependent to a growing extent on economic and human values, and in such diverse problems as the prevention of unemployment or of wide fluctuations in economic activity, the provision of better housing, or the suppression and cure of disease, purely national action cannot find a complete solution. The mechanism of international co-operation which has been built up by the League is rendering invaluable service to the world as a whole in meeting these needs. Moreover, the way in which the world is becoming closer knit, in spite of political severance, and the growing similarity of the form of economic structure in different countries and of the difficulties for which they must find solutions, are powerful factors even at the present time in stimulating the expansion and development of the League's work in such fields, and in the scientific approach to such questions as nutrition, housing and health on an international scale.

International discussion offers a further advantage in affording a safeguard against the effect on governments of sectional influences at the expense of the general welfare. The growing material and intellectual demands which men make on life, the consciousness that a better use of the scientific and productive resources of the world could improve their living conditions out of all knowledge, the impatience for some real and concerted effort to raise the standard of living near to what it might become, are yet further factors reinforcing the tendency towards international co-operation. Indeed, it may well be expected that the very sacrifices and renunciation which citizens in Great Britain have so willingly made of the advantages which modern science had placed in their hands, whether in the domain of communications and transport, lighting, entertainments, which within a couple of decades or so we had come to take for granted, will stimulate a further and more determined effort after the war both to extend such advantages and by international co-operation to make them secure from interruption again.

The picture which this report gives of the variety and success of the League's work in the checking of epidemics, the control of disease, the suppression of the traffic in opium and other narcotics, and in women and children, or the regulation of international communications or the pooling of experience and investigations in such problems as nutrition or the causes of economic depressions, is not altogether unfamiliar to many scientific workers. The present report, however, gives a concise summary of the real advantages of the League's organization and the way in which it is able to make a uniquely economic contribution. Its resources enable it to collect and sift evidence drawn from all over the world, to obtain the services of the best experts and arrange meetings between them, and to provide the essential links between experts and those responsible for policy, as well as opportunities for statesmen to meet and discuss their policy, and machinery for the conclusion of international agreements. As Mr. Cordell Hull recently wrote to the Secretary-General: "The League of Nations has been responsible for the development of mutual exchange and discussion of ideas and methods to a greater extent and in more fields of humanitarian and scientific endeavour than any other organization in history."

Considerations such as these have led the Special Committee, of which the Right Hon. S. M. Bruce was chairman, to its proposals for extending the work of the League in this field and increasing its efficiency. It recommends that a Central Committee for Social and Economic Questions should be created to supervise the work and co-ordinate the efforts of the many different agencies engaged in it. This committee would direct and supervise the work of the League committees dealing with social and economic questions, and appoint the members of the standing technical committees so far as possible. It is further proposed that, to give States which are not members of the League the opportunity of the fullest co-operation in the work itself as well as in its direction, non-members of the League should be represented on the committee on the same footing as the member States, and that the committee should have power to co-opt non-official members experienced in economic and social affairs.

These proposals should facilitate a clearer separation between the political and non-political work of the League, and provide a permanent basis for the development of the economic and social work of the League. Apart from this development, such separation may be of value in retaining the structure of the organization if, after the war, it is expedient to make a fresh start to secure the goodwill and co-operation of Germany and other nations.

Nor is it only on the social and economic side that we have been reminded of the forces still working for international co-operation. Two papers prepared for presentation before the Division for the Social and International Relations of Science at the Dundee meeting of the British Association deal with the question of international intellectual co-operation. Prof. Gilbert Murray describes the purpose and organization of the Committee of Intellectual Co-operation and the various types of conference organized under its auspices or in association with other bodies, such as the International Labour Office. He refers, for example, to the study of science and social relations, such as the effect of scientific invention on industrial conditions, and the proposal of the International Labour Office to include men of science in its conferences.

Prof. Gunnar Dahlberg's paper is mainly concerned with the question of translation of scientific papers. Organization of the facilities of translation would, he considers, facilitate international co-operation for the smaller countries, and Prof. Dahlberg supports the idea of a world language in science. He also stresses the value of informal conferences on special problems between leading men of science from different countries.

If the possibilities of international conference on any scale are remote at the moment, the movements and tendencies in the field of intellectual co-operation, no less than in the economic and social sphere, should remind us of the hard thinking and preparation which are yet to be done if opportunities are to be seized as they present themselves.

We have entered on this struggle to prevent further encroachments on freedom of thought and speech and investigation; but freedom can be endangered even in such a cause as that for which we contend. If the fruits of victory are ultimately to be reaped, we must bring to the struggle not merely the full force of our moral and material resources, but also constructive and imaginative statesmanship ready to build on whatever remains from the present wreckage of our hopes. Science, at least, has given men a vision of the world that might be when man's moral and spiritual development is in keeping with his material advance. If that world is ever to be realized, scientific workers, amid the stress of the present emergency, must guard zealously their loyalty to truth, not less than their belief that science transcends national frontiers, and that mankind will only enter on its full heritage through international co-operation and understanding, and the mutual respect and good faith upon which alone such co-operation and understanding are possible.

AN ENCYCLOPÆDIA OF CHEMISTRY

Thorpe's Dictionary of Applied Chemistry
Vol. 3. Chemical Calculations—Diffusion. By Prof. J. F. Thorpe and Dr. M. A. Whiteley. Fourth edition. Pp. xxiv + 608. (London, New York and Toronto: Longmans, Green and Co., 1939.) 63*s*. net.

THE third volume of Thorpe's "Dictionary" opens with a short sermon by Dr. Johnson intended especially for adverse critics. To one who has not, perhaps, been too complimentary in the past, it is indeed gratifying to find that a few chance words have deserved so much attention, for the reviewer of an encyclopædic work such as the present, not being omniscient and having no collaborators, must needs confine himself to general aspects, although, on occasion, he may be permitted to indicate an error. He can but put forward what he believes to be the views of a section of readers and make suggestions which he considers will improve the later volumes.

It was mentioned that, to justify the issue of a new serial which might become a millstone around librarians' necks, matter of exceptional character would have to be provided, and this condition appeared scarcely satisfied by the first two volumes. Another ground for complaint was that, in spite of the title and the crying need for an up-to-date book on industrial processes, the general impression of these volumes was that of a text-book on organic chemistry.

It seems too much to hope that these remarks have borne fruit, but the fact remains that the third volume is something different. It is possible to turn over page after page without seeing an organic formula, and references dated 1936, 1937 and even 1938 abound, while, when preparing a list of the more important contributions, it is necessary to write "new" with almost monotonous regularity.

The volume opens with an excellent article on chemical calculations, a title which unfortunately does not indicate the scope of the contents. It includes triangular co-ordinates, nomograms and graphical methods of calculation in general, or, as the author puts it, "methods of saving time in calculating". It should be read by all chemists, and physicists too. Other general articles include "Chemical Warfare", beginning with the words: "Chemical warfare is prohibited by the Geneva Protocol of 1925," but none the less doubled in length since the issue of the supplement and containing a concise account of the subject with good bibliography; "Colloids", a brief but clear survey; "Colorimeters", a lucid treatise on modern instruments, their uses and the theory of colour measurement, which should be in the hands of all those who have to deal with the subject; "Condensers", in which the author has shown his ability to condense matter other than vapours by discussing in eight pages, largely occupied by illustrations, the history of commercial and laboratory condensers, types for special purposes, condensers used in industry, the corrosion of condenser tubes and the theory of condensation, the whole being interspersed with more than one hundred references; "Co-ordination Compounds", extended from the supplement and brought up to date to form a comprehensive review; "Corrosion and Protective Measures", occupying thirty-two pages, which must perhaps receive a prize for the admirable way in which it deals with the many aspects of this controversial but important subject; "Crystallisation", a good article with adequate diagrams, dealing with the principles underlying what was until recently an empirical process; and, finally, "Diffusion", in which the phenomenon is considered mainly from the laboratory aspect—in view of its importance in industry, a more comprehensive treatment would have been desirable, but perhaps there is to be an article on diffusional processes.

There is but one black spot, mentioned on a previous occasion, and that is the risk that these valuable articles may escape notice. The man in the street wanting information on mustard gas would think he must wait some years for M or G or P, while the chemist might look up "Chlor" but obtain no satisfaction. Even if an abbreviated index is not possible, a list of general articles to date would be of much service to the reader.

The longer articles dealing with individual substances or groups of substances have been mostly rewritten, in many cases by those engaged in actual manufacture, and a fair number of new diagrams has been introduced. A particularly pleasing example is "Benzol Recovery", while "Chloroform", although taken from the older edition and ruthlessly mutilated, is still able to remain a gem. It is difficult to say whether "Cinchona Alkaloids" or "Cyanides" is the outstanding contribution in this class. Each occupies some fifty pages and summarizes our present knowledge with a conciseness not likely to be found elsewhere. A new contribution, "Coal Tar", with explanatory diagrams, serves as a good introduction to modern distillation methods, while "Chlorine", partly rewritten and enlarged, contains among much other information a useful account of electrolytic cells. Space does not allow discussion of all the three hundred and ninety-five headings dealt with, and thus it must suffice only to mention "Cobalt" and "Copper" with their important alloys, "Citric Acid" and "Cider" among the natural products, and "Cyanine Dyes", "Diazo Compounds" and "Cocaine" with its derivatives, as illustrating some recent developments of organic chemistry. Finally, "Deuterium", practically unknown when the last edition was published, has now an extensive literature which has been collected and abstracted to give a very complete account of the properties of the element.

To summarize: volume 3 appears to be a great advance on its predecessors and to approach very nearly the ideals of its authors. May the high standard they have set up continue and may they find, with Dr. Johnson, that "useful diligence will at last prevail". H. E. W.

FIRST YEAR UNIVERSITY BOTANY

An Introduction to Botany
By Prof. Arthur W. Haupt. (McGraw-Hill Publications in the Botanical Sciences.) Pp. xii+396. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 18*s*.

An Introduction to Botany
with Special Reference to the Structure of the Flowering Plant. By Prof. J. H. Priestley and Lorna I. Scott. Pp. x+615. (London: Longmans, Green and Co., Ltd., 1938.) 17*s*. 6*d*. net.

A GOOD many university botany schools have now published their first-year teaching courses as text-books. They vary strikingly in subject, but this may make little ultimate difference as gaps can be made good in the next two years; it may also matter very little whether the wide survey method or intensive study on 'types' is used. The student's attitude to his work at the end of the year is what is of fundamental importance.

All teachers must have seen a freshman of promise, starting with a childlike thirst for knowledge, who in a year or two became dull, seemingly bent on acquiring the minimum of knowledge (and very likely failing in that). However little the teacher is to blame, it may well be that this disaster would have been prevented by other methods. Of great importance, too, is the student's attitude to his practical work, whether he makes a record of his observations which he is prepared to trust when, for example, it conflicts with book or lecture. Perhaps a student cannot greatly increase his inventiveness and power of logical thought; but these virtues can be put to sleep by wrong teaching.

While it is the nature of a text-book to supply facts, some writers show their preoccupation with education (as apart from instruction) more obviously than others.

(1) Here are two books, both good. Haupt's shows a very normal balance and excels in the simple way every subject is treated

There is no doubt that a student who wanted a book to supplement his lecture notes would like it; and if his botany ends with the year, it may be just right. It is an easy book because it is well arranged and well expressed, and sometimes because things are made to seem easier than they are; for example, in the section on transpiration the reader would certainly suppose that light causes stomata to open through increased sugar formed simply by their own photosynthesis. It may be well to save a muddle by withholding queer facts, but only if the reader is made to realize that he has not anything like the truth. It must be more difficult afterwards to teach the mechanism of a stoma where a slick and wrong notion is held than where there is none. On the other hand, it may be that the student will be so interested and encouraged by his ability to understand that he will surmount his difficulties none the worse.

(2) Priestley and Scott's book is unusual in balance; nine tenths is on the flowering plant, though the continuation of the title "with Special Reference to the Structure of the Flowering Plant" is barely just, for structure is only considered in relation to function. Tables of real data are included; they may not always prove their point, but they are exactly the sort of measurements students can make, and they are as ragged as an honest student's results. It may be said that this book is unique in fostering scientific honesty by glaring examples. Much of the subject matter is equally fresh, and the teaching reader is sure to find ideas to incorporate in his own course.

Difficulties are faced wherever they arise, but scarcely so admirable is the way some are met when there is no apparent need; there is, for example, some discussion of plastochrones and the significance of Fibonacci phyllotaxis. Causal explanations are given throughout, but sometimes on an inadequate basis. It is said that the modification of gorse leaves to spines "appears to be due to lack of sufficient water", and as evidence is given the statement that in wet seasons gorse shoots often revert to the flat seedling foliage. Gorse, however, develops fierce spines in western Ireland (where it is surely wet enough) and in gardens along with soft-leaved plants. It is, however, only just to say that this is an extreme example, and the risk to the student is the less since a causal explanation at once suggests an experimental test, or original observation.

T. M. H.

EXPERIMENTAL EMBRYOLOGY

Form and Causality in Early Development
By Prof. Albert M. Dalcq. Pp. vi+197. (Cambridge Biological Studies.) (Cambridge: At the University Press, 1938.) 12*s.* 6*d.* net.

THE fertility of its ideas and the widths of its interests have combined to make the Brussels School of Embryology under Prof. Dalcq a centre whose work and activities are of the greatest interest and importance to all biologists. It is therefore particularly valuable to have Prof. Dalcq's views succinctly set forth in this volume which he has written in English.

Few are the aspects of experimental embryology to which the author and his colleagues have not made original contributions, and the present work is, essentially, a synthesis of modern views based on experimental evidence of the time-honoured problem of the causality of form-production in ontogenetic development. Space is lacking in which to do justice to the many important problems raised in this book, such as the progressive development of the inductive power of the organizer, the potencies of the ascidian egg, or the nature of the phenomenon of regulation. But attention must be paid to what is, really, the point of chief interest and importance of the book, namely, the attempt to formulate an explanation of the repartition of the presumptive organ-forming regions of the chordate egg. This the author ascribes to the combined effects of processes associated with a gradient in the cortex of the egg having its high point at the site of normal formation of the dorsal lip of the blastopore, and a gradient in the yolk the repartition of which is under the influence of gravity. A dorsal lip invaginates at the normal site, or at a place nearest this site in contact with yolk, and sets up an organizing centre. By introducing the concept of threshold qualitative response values in the gradient field set up by the above-mentioned gradients, a formal explanation can be arrived at of the distribution of the presumptive notochord, mesoderm, neural plate, and other territories.

The concept is nothing if not bold, and extends in many ways the views which have now for some time been associated with the name of Child. If Prof. Dalcq's views can be substantiated, then indeed a capital step will have been taken. The author would be the last person to deny the necessity for further experimental evidence to establish his hypothesis beyond question; and there are difficulties. But already his hypothesis enables acceptable interpretations to be given of results which have seemed baffling, such as

Yamada's experiments on the differentiation of presumptive notochord into structures of 'sub-notochordal' rank; or Lopaschov's demonstration of the differentiating powers of massed organizers.

Another very important aspect of Prof. Dalcq's position is his derivation of gradient fields from pre-existing oocyte organization and not as a result of the action of directional external factors. This has an important bearing on the problem of preformation and epigenesis, and also points the way to a field of new work on gametic cytology. But enough will by now have been said to bring to the notice of all biologists the fundamental importance of Prof. Dalcq's work.

G. R. DE BEER.

FORESTRY IN INDIA

Manual of Indian Silviculture

Part 1: General Silviculture, by H. G. Champion; Part 2: Silvicultural Systems, by Sir Gerald Trevor. Pp. xv+374+33 plates. (London: Oxford University Press, 1938.) 30*s*. net.

SINCE the establishment of the Forest Research Institute at Dehra Dun in 1906, Indian sylvicultural knowledge has advanced rapidly. Two manuals of Indian sylviculture had been written at different times before then, but these have long been out of date. The appearance of the present work, therefore, is to be welcomed. Its joint authorship does not imply collaboration. The two portions of the book—(1) "General Silviculture", by Champion, and (2) "Silvicultural Systems", by Trevor—might equally well, and perhaps with advantage, have been published as separate works.

Champion's contribution, which occupies more than three-quarters of the whole, breaks much new ground, and its general arrangement is logical. The subject matter is dealt with in eight chapters: i, the locality factors of the forest; ii, growth and form of trees and crops; iii, tree and crop physiology; iv, forest composition and distribution; v, natural regeneration; vi, artificial regeneration; vii, afforestation; viii, tending. Each chapter is subdivided into well-defined sections and subsections which facilitate reference, and although the style is terse and sometimes even brief, a comprehensive list of references to literature appears at the end of each chapter. In this way much ground is covered within a reasonably small compass, while the reader is put in possession of the necessary references for further details. While general principles are expounded, the author is at pains to apply them strictly to Indian conditions.

Under locality factors, special attention is paid to the important question of the soil. Admittedly our knowledge of forest soils, particularly in the tropics, is as yet far from complete; nevertheless, this section should prove of much value to students of tropical sylviculture. A noteworthy feature of tropical forest soils is the absence of decayed leaf litter, owing to the rapid decomposition in warm climates; this may be observed even in rain forest with a yearly production of 100 tons of fresh organic matter per acre. Typical *p*H values are given for different forest soils in India, the most acid being red laterite (4·5) and the most alkaline black cotton soil (8·7–9·0) and alkali soil (9·6–10·4). In the irrigated areas of the Punjab, it has been found that soils with *p*H exceeding 8·5 cannot be satisfactorily planted with *Dalbergia sissoo*; up to 9·0 several of the indigenous trees can grow, but above 9·5 the soil is barren.

Among the many biological questions relating to forest trees and crops that are dealt with may be mentioned conditions of flowering and seeding, seed dispersal, the establishment of seedlings (including the phenomenon of 'dying back'), root competition, the inheritance of parental characters, and water and light relations. Part 1 ends with a useful discussion of artificial regeneration and tending, and stress is rightly laid on the importance of shifting cultivation as a basis for the formation of forest plantations.

Part 2, on sylvicultural systems, by Sir Gerald Trevor, following the arrangement and substance of Troup's "Silvicultural Systems", enumerates the various systems developed in Europe, and gives examples of the application of these systems to Indian forestry. It is of particular interest to note how the systems of Europe have been adapted successfully, with suitable modifications, to the varying conditions in India. Leaving out of account the management of bamboo forest, which does not concern European forestry, and the rough selection fellings employed as a provisional method of working, it may be said that, apart from local modifications, there is no Indian system described in the book that is radically different from one or other of the recognized systems of continental Europe. This is ample testimony to the soundness of the policy at one time in force of including in the training of probationers for the Indian Forest

Service a period of practical study in those European countries in which the standard sylvicultural systems are well exemplified. Some of these systems are now so well established in India that they furnish examples equal to anything to be found in Europe: this only serves to emphasize India's indebtedness to Europe, a fact that is sometimes overlooked.

The style of the book is attractive and the illustrations are good, though in some of the titles the omission of the locality to which they refer detracts somewhat from their interest.

THE HYDROLOGY OF THE UPPER WHITE NILE

The Nile Basin

Vol. 5: The Hydrology of the Lake Plateau and Bahr El Jebel. By Dr. H. E. Hurst and Dr. P. Phillips. (Ministry of Public Works, Egypt: Physical Department Paper No. 35.) Pp. x+251+103 plates. (Cairo: Ministry of Finance, 1938.) P.T. 100. 20*s*.

SINCE 1931 the Physical Department of the Egyptian Government has been issuing at intervals the volumes of a publication "The Nile Basin", written by Drs. H. E. Hurst and P. Phillips. The earlier volumes have contained descriptive matter and statistical records of hydrological observations of the Nile and its basin. The series has now been crowned by the volume under review, which summarizes and discusses the results of thirty years' river survey in the Sudan, upon which work Egypt has spent money both generously and fruitfully.

The excellent and numerous maps and diagrams that accompany the text have been reproduced by the Survey of Egypt, from which the Physical Department has sprung. One is reminded by this instance of co-operation of the principle advocated before the British Association in 1929 by Brigadier E. M. Jack, that the several survey branches of any country's administration should be as closely related as possible.

"The Nile Basin" is a book of a type of which unfortunately far too few examples get published. Mankind is comparatively well supplied with information as to the resources of the heavens and the earth itself but, as was noted by Galileo, knows little of the freshwater resources of the globe. So much is this the case that, when anything on the subject is reported in a British technical journal, the indexer usually is at a loss to classify it suitably and places it under some such heading as 'Water Supply', that is, distribution, whether the resources have been put to use or not. In this connexion, reference may be made to a recent Stationery Office publication, in which on an advertisement page the Surface Water Year-book of Great Britain, 1935–36, is placed under the heading of River Pollution and Fisheries.

The motives of modern Egyptian river-studies are the same as those for which the Roda gauge at Cairo has been read since A.D. 620, namely, irrigation and defence against floods. Without entangling the reader deeply in the problems of the Egyptian Irrigation Department, the authors frequently discuss their data with reference to those problems.

The task of surveying the Upper Nile is a formidable one, because of the tangle of lakes, channels and swamps in which the river-flow is gradually accumulated and through which it passes to Malakal. As the result of these physical conditions, any scheme for the conservation of the river-water in those regions in the interests of far-away Egyptian agriculture brings many factors into play. There is, however, a practical limit to the amount of survey that can be undertaken. Great care and skill have, therefore, to be exercised in extracting the maximum of accurate data for the testing of the schemes prepared.

In performing their task, the authors have, however, placed hydrologists as well as river-engineers in their debt, not only by furnishing well-arranged records of the river-system and its behaviour but also by discussing various problems and phenomena, such as the time of travel of changes of river-level and discharge; sunspots in relation to the water-levels of Lake Victoria; flow through and water-losses in swamps; the backwater effect of large rivers on one another; and gauge-discharge relationships as observed at various points on the Nile. Orthodox forms of statistical analysis have been used to an extent that is otherwise very rare in studies of this great river.

Dr. Phillips' death unfortunately occurred whilst this book was in draft form. Although hydrologists must deplore the premature loss of this valued worker, they can nevertheless rejoice as he surely would have done that this admirable record of the river-survey work of Dr. Hurst, his staff and the Egyptian Irrigation Department has now by publication been given a wider audience and endowed with permanency.

W. Allard.

SEVENTH INTERNATIONAL GENETICAL CONGRESS

THE chief qualifications demanded of those who undertake the organization of an international scientific congress in these days would seem to be an unwarrantable optimism and a complete disregard for current political events. At no time during the last two years has it ever been certain that the International Genetical Congress would meet, and now it is indeed surprising that it ever met.

It will be remembered that the Permanent International Committee appointed by the Sixth Congress at Ithaca in 1932 accepted the invitation of the Russian geneticists to hold the next Congress in Moscow in 1937. Difficulties arose, however, which made its postponement necessary. Late in 1937, the International Committee had reason to doubt that the Congress could be held in Moscow even in 1938, and found it necessary to seek invitations from other countries. The committee of the Genetical Society of Great Britain was informed that if we in this country were prepared to take over from the Russians, we should be rendering both the science and the International Committee a very great service. Being assured that it was quite impossible for the Congress to meet in Moscow in 1938, the Genetical Society of Great Britain offered, in October 1937, to stage it in Great Britain in 1939 This offer was eagerly accepted.

The committee of the Genetical Society formed itself into an organizing committee and decided that the Congress should meet in Edinburgh. F A. E. Crew was appointed general secretary. Since N. I. Vavilov would have been the president of this Congress had it been held in Moscow as was intended, and since we wished to indicate in the only manner available to us our great respect for him personally and our ardent desire for the active co-operation of the Russian geneticists in the affairs of the Congress, an invitation was sent to Vavilov asking him to continue in the presidency.

During 1938 and the first half of 1939, the programme of the Congress slowly took shape. At times the organizing committee had reason to think that its was a hopeless task; at others it was greatly encouraged by the eager co-operation extended to them by geneticists from all over the world. A programme built up of more than four hundred papers of quality was ultimately issued, whilst in London, Cambridge and Edinburgh preparations for the reception and entertainment of some four hundred foreign guests were completed. Yet all the while doubt lurked in the minds of all of us. It was obvious to all that the day was not far distant when the flickering lamps of science would be dimmed, and the only question that concerned us was when this day would dawn. Should we be permitted to carry this Congress to its successful conclusion before we were required to leave the forges of knowledge and use tools that we had made, for unworthy and damnable purposes?

On the morning of August 23 there gathered for the first meeting of the Congress some six hundred geneticists drawn from fifty-five different countries. There could be no grander measure of the devotion that men of science give to the science they serve than this. They met in days heavy with anxiety, to consolidate the ground won by them and their colleagues during the last seven years. The Congress had met, but it lacked a president, for, a fortnight previously, information was received that no one from the U.S.S.R. would be attending. This was a wound which at the time seemed mortal, for it had been hoped that not only would Russia supply a president but also that fifty or more papers of outstanding quality would be presented. However, the vitality of the Congress was such that it survived, and for two days into its rooms none of the loud murmurings of the outside world entered. Looking back on those days, they now seem to have been a dream of what the world itself might be were all men reasonable.

It is true that according to the records there were Americans, French, Germans, Poles, and all the rest of a great geographical and political variety, yet these were divided by no barrier of language or of prejudice. They formed one harmonious whole, moved by a common purpose, to advance a science, to serve mankind, to cultivate a fellowship. But the murmurings outside grew in intensity, and towards the end of the second day the air became disturbed, and everyone began to remember his private responsibilities and duties. The first group to be seriously affected was the German delegation (34 strong), which received advice that it would be desirable for them to think of returning home. This advice they resisted until it became quite certain that if they delayed longer they might encounter very serious difficulties in transportation; and so, most regretfully, and bearing with them the good wishes of their colleagues, they bade us farewell. At the same time, owing to mobilization of the Dutch army, the delegation from the Netherlands (17 strong) decided that it was desirable that they also should go. From that moment onwards the citizens of Edinburgh looked upon the Congress as a trustworthy barometer. Hourly inquiries as to whether or not the Italians, the French and the Poles were still with us were received, and Edinburgh was comforted when it could be told that the French and the Poles were remaining with us, and that the Italians had no intention of departing.

The programme, of course, was sadly crippled by this time, and for a while the organizing committee considered the question as to whether or not, in the circumstances, it would not be advisable to bring the Congress to an abrupt end. However, the Congress itself decided that it should continue. There was little else that we could do save to indicate, by continuing, that science was worth serving even in days like these, and that it, of all things, offered the most enduring good to all mankind. But the Congress was shortened, for Sunday was made a working day. A brave gesture this, for it will be remembered that Edinburgh is the capital of Scotland. As things turned out, this decision was more than justified, for the meetings continued to be very well attended right to the end, and daily the congressists sat down to mighty repasts. Looking back upon the sessions from this short distance, it would seem that not one of them was remarkable for the announcement of any startling discovery, but that they were immensely useful in that, during them, differences were bridged and new lines of advance were traced.

The organizing committee received repeated expressions of congratulation for the way in which the Congress affairs were conducted. Those who congratulated us seemed to be unaware of the obvious fact that the quality of a Congress is determined not so much by its organization as by the personalities of its adherents. On this occasion we were more than ordinarily fortunate. From a great many countries there came strong delegations bringing contributions of knowledge, of friendliness, of charm. It was they who made this congress successful. To the Germans, to the French, to the Italians and to the Poles we are indeed indebted. They came at great personal inconvenience to our aid, and they have left behind them most happy memories. The coming of an American contingent, 130 strong, made the success of the Congress inevitable. But it is too much to expect that the welcome they received would compensate them for the distress that they endured when the Congress ended, for then they found themselves stranded in Great Britain with no immediate hope of return to their own. Already at least seven of them have been exposed to the gravest danger, for these were passengers on the *Athenia* and their fate at the moment of writing is not known. Some forty others have still to make the dangerous passage.

At the first business meeting of the Congress, F. A. E. Crew was elected to the presidency rendered vacant by N. I. Vavilov's absence. A Permanent International Committee, consisting of C. L. Huskins (Canada), O. Winge (Denmark), Boris Ephrussi (France), Von Wettstein (Germany), F. A. E. Crew (Great Britain), A. Ghigi (Italy), M. J. Sirks (Netherlands), Otto L. Mohr (Norway), G. Dahlberg (Sweden), A. Ernst (Switzerland), M. Demerec (United States of America), was appointed. This committee later elected F. A. E. Crew as its chairman.

At the second meeting of the Congress it was agreed that, in the circumstances, it was quite impossible at this particular time for the International Committee seriously to consider invitations and to decide as to the time and place of the next congress. It was intimated that invitations had been received from Italy and America. The International Committee was given authority to designate the time and place of the next congress at some later date.

Following a motion brought forward by the International Committee, the Congress decided that it should not be regarded as essential or necessary for future congresses to publish *Proceedings*. This decision was reached because it was recognized that, in the past, a number of invitations to meet therein had not been received from several countries on account of the expenses that are associated with the publication of the *Proceedings*. It was recognized that complete autonomy must be given to the actual organizing committee of a particular congress as to whether or not *Proceedings* of that congress should be published.

The Congress considered the setting up of an international committee which would devise a scheme whereby animal and plant stocks of genetical importance could be maintained in times of emergency. The International Committee was asked to consider the matter and set up a committee for this purpose.

During the course of the Congress a group meeting was arranged for the discussion on the statistical requirements of the student of genetics. At the end of this meeting the following resolutions were passed:

(1) That the teaching of statistics should be carried out in conjunction with the teaching of practical genetics.

(2) That elementary statistical methods, in particular tests of significance and their validity, should be included in the ordinary mathematical courses given at secondary schools.

(3) That the General Secretary of the Seventh International Congress of Genetics be requested to transmit copies of resolution 2 to any educational bodies which he considers may be able to assist in its fulfilment.

(4) That the genetical societies of countries

represented at the Seventh International Congress of Genetics be requested to discuss the teaching of statistics in relation to genetics and to transmit their final resolutions to the next congress.

In connexion with the Congress, a meeting of mouse geneticists was held on August 24 to consider a set of nomenclature rules drawn up by a recently formed Committee on Mouse Genetics Nomenclature and to discuss details of a Mouse Genetics News Service. The director and staff of the Roscoe B. Jackson Memorial Laboratory in Bar Harbor, Maine, U.S.A., have offered facilities for the publication in mimeographed form of the *Mouse Genetics News*. It was suggested that a register of stocks and the various pure lines should be drawn up; this should end the confusion in the naming of pure lines used in various laboratories which has arisen during the last few years. Stock lists of all the laboratories concerned should be published from time to time. It was further suggested that notice should be given by a laboratory before any stocks are discontinued; it has happened several times in the past that valuable material has been irretrievably lost, because every laboratory has relied on other places for its maintenance. The News Service should also arrange for exchange of stocks, and it is hoped that its activities may be extended to rabbits and other rodents. The meeting also discussed the establishment of centres, preferably in the United States, for the maintenance and safe keeping of stocks, particularly of genes (pathological and otherwise) which are not purposely kept by the fancy. It was urged that this matter should receive the immediate consideration of the News Service, and that an appeal should be made to the Carnegie and Rockefeller Foundations for financial assistance. F. A. E. CREW.

MEASUREMENT IN PSYCHOLOGY*

BY R. J. BARTLETT

IN the opening paragraph of "Psychology Down the Ages", Prof. C. Spearman concludes a list of difficulties facing any who seek to define psychology, with the questions: "Do the data at its disposal include what can properly be called 'measurements'? Is it, or can it ever hope to be, or should it as much as try to be, a systematic science at all?" Dr. William Brown, in the realm of medical psychology, answers the first question in the negative. Forced into metaphysics, he writes: "Determinism, although a postulate for psychology, cannot be accepted as anything proved. In physical science there is empirical proof of it to a certain extent through measurement. By measurement we can prove to a certain extent, within certain limits of error, the conservation of mass, the conservation of energy. . . . But there is no measurement of that sort possible in psychology. . . . The observations of psychology are primarily qualitative, not quantitative." But the writer of "Essentials of Mental Measurement" could not leave it there. He added a footnote: "But mental measurement, in a derived form, is possible in the domain of mental tests and of the psycho-physical methods."

The conflict between philosophy and experimental psychology, thus exemplified, is of long standing. Malebranche argued that mental states could be distinguished qualitatively, but not quantitatively. Leibniz declared that mathematical treatment was impossible in psychology as it lacked continuous magnitudes. Kant said that psychology possessed no mathematical magnitudes for the reason that, "whereas the phenomena of matter possess two variables, space and time, those of mind have only the single one, time". For these and many later philosophers psychology possesses neither measurable phenomenon nor the means to measure. Still worse! Some physicists seem to have reached the same conclusion. For them measurement is impossible in psychology.

Notwithstanding criticism from philosophy and physics, the word measurement is deeply imbedded in the literature of psychology, and of late years its use has been greatly on the increase. Experimental psychology is little more than fifty years old. Galton's "Inquiries into Human Faculty" appeared in 1883, Wundt went to Leipzig in 1875, Weber died in 1878 and Fechner in 1887. Since then an ever-growing body of workers has been applying experimental method to psychological problems and developing its own methods of measurement and mathematical treatment of data obtained. Contemplating this work against the declaration that measurement is impossible in psychology, Prof. Spearman comments: "But the path of science is paved with achievements of the allegedly unachievable. And in point of fact, mathematical treatment is perhaps just the region where psychology has made its steadiest and most surprising advances." My task is to attempt a review of experimental psychology that will reveal the senses in which the word measurement is being used by psychologists.

---

* From the presidential address to Section J (Psychology) of the British Association, delivered in Dundee on September 1

Psycho-physical Measurements

When we turn to actual measurements being made in psychological laboratories, we find in use metre scales and foot rules, balances and weights, chronoscopes and stop watches, resistance boxes, galvanometers, photometers and any other measuring instrument that ancient wisdom or modern physics has made available and happens to be of service in the task in hand.

One general group of tasks consists in measuring the results of bodily activity carried out under controlled conditions. Take as an example the product of a person's behaviour when asked to draw lines on blank foolscap paper of length equal to half the width of the paper. In one experiment 2,048 such lines were drawn and measured. It is probable that no two lines were exactly the same length, and that measurement to 0·01 mm. would have proved this, while obscuring a law binding them together.

Choosing a coarser unit, we measure to the nearest millimetre and find 92 lines of 103 mm. length at the modal value of results scattered from 69 mm. to 135 mm. Relative to the material our unit is still fine, so by addition we find the numbers of lines that would have fallen into each group had we measured with units 2, 3, 4, 5 and 6 mm. respectively. With increase of the size of unit the numbers approximate more and more closely to a smooth curve. Further, as we take out the figures for measurement with a unit of 6 mm., we recognize in them an approximation to the terms of the binomial expansion $(1+1)^{11}$. Then, using the slightly smaller unit of 5⅞ mm., we obtain a very close approximation to the binomial point curve. For a particular case we have established the fact that by suitable choice of unit our experimental data fall into groups closely approximating to the binomial distribution of their number, 2048. This is but a particular case of a general law.

The Gaussian continuous function, commonly called the *normal curve* or *curve of error*, in the form

$$y = \frac{N}{\sigma\sqrt{2\pi}} e^{-x^2/2\sigma^2}$$

gives close approximations to the values of binomial distributions, and is usually taken to represent the law of distribution of the results of the bodily expression of mental intention. The frequency with which results of this nature are obtained in psychological experiments leads to the conclusion that an appreciable scatter is an essential feature of our data, and that, while the old-time physicist or chemist can rest satisfied with the mean of two determinations, we must make at least fifty before we can be reasonably sure of the values of our constants. Experimental psychology could have made little progress without accepting what Dr. Darwin, last year, in his presidential address to Section A, called "the fuzziness inherent in absolutely all facts of the world", when he was arguing "that the subject of probability ought to play an enormously greater part in our mathematical-physical education".

Kant reached the conclusion that mind had but one variable—time. Without accepting his conclusion, we can concur in the importance of the time factor in mental happenings, and appreciate the part played in psychology by the Wheatstone-Hipp chronoscope, stop watches and other instruments for measuring and recording time intervals. Starting from comparatively simple beginnings, reaction times of more and more complex mental activities were determined, and the chronoscope has become for the psychologist what the balance is for the chemist.

It would seem undeniable that intensity is a characteristic of sensory experience. When we attempt to evaluate this quantitative element in sensation we are met with difficulties. First comes the fact that the same material object may be perceived by sensations that vary greatly in intensity. The intensity of experienced sound of an express train is as a rule different for a passenger comfortably sitting in it and for a would-be passenger standing on the platform as it rushes through a station. The intensity of the noise of a ticking clock sinks below the threshold when we are engaged in an absorbing task, but the energy output of the clock remains reasonably constant. The same source of stimulation occasions different intensities of sensation according to the subjective attitude of the recipient of the energy falling upon the sensory organs. To secure consistent results it is necessary to control the conditions, and in experiments involving sensation-intensity this is done by arranging that the subject shall give undivided attention to the stimuli. The maximal intensity thus obtained is accepted as constant for the given stimulus.

Normally we do not discriminate the intensity of the sensation, nor are we interested in the particular sensation itself. Our interest may be in the pleasure tone of the whole sensation complex, as when enjoying music or a glorious bank of flowers, but, more often, our interest is in the properties of the external objects that occasion the experience. The lightning's flash, the trumpet's blare are ominous portents, rather than intense sensations. This preoccupation with the things of the external world has given us science but makes introspective analysis of experience difficult. It endows sound, light and matter with 'intensity' which we proceed to measure with acoumeters, photometers and a balance. For the psychologist, however, these measurements are only of interest so far as they may help to throw light on the problems of sensory experience.

Early in the life of experimental psychology the smallest change in the stimulus value that could be appreciated in sensation became the subject of inquiry and, for the determination of this difference threshold, difference limen, least perceptible difference or just noticeable difference, the psycho-physical methods were developed and gave to psychology a technique the wide serviceability of which does not even yet seem to be fully appreciated.

[Mr. Bartlett here discussed the Weber ratio]

PHYSIOLOGICAL INVESTIGATION

Another branch of experimental psychology busies itself with the physiological concomitants of emotional experience. On a smoked drum record of a subject's breathing, measurement can be made of frequency and amplitude, and changes therein can be compared with introspection records to find out their meaning. The inspiration-expiration ratio, with varying emotional states, shows marked variations from the average value, rising to as much as three times that value in 'amazement' and sinking to about half the value under the sense of guilt or shame awakened by conscious misrepresentation or wilful falsehood. These changes in the ratio of inspiration to expiration are accompanied by marked changes in frequency, amplitude and form, which result in characteristic curves that the eye can read and interpret without recourse to the millimetre scale and time record. The whole profile, rather than its analysis, is diagnostic.

INTELLIGENCE TESTS

An entirely different method of measurement had by 1920 reached the stage where it could not be ignored. Intelligence tests were being widely used, and the Board of Education set up a consultative committee to report "on psychological tests of educable capacity and their possible use in the public system of education". The report appeared in 1924, and the principal findings of the committee were: "That up to the present the only kinds of psychological tests of educable capacity that have been sufficiently developed to be of much service in schools for the purpose of diagnosing and assessing such capacity are tests of 'intelligence', standardized scholastic tests, and to a less extent vocational tests". Let us consider the first of these.

The foundations of the method are laid in Binet's happy thought of 'mental age' and Spearman's application of methods of correlation to psychological data. Prior to Binet's work, testing had been confined almost entirely to tests of sensory discrimination. Spearman proceeded to calculate correlation coefficients between the results of such tests and estimates of intellectual ability. Binet, "instead of measuring the intensity of simple faculties", set out by tests "manifold and heterogeneous . . . [to] measure acts of adaptation . . . to determine how many years an individual is advanced or retarded". His measure is a time measure based on the normal development of intellectual ability. Originally his "manifold and heterogeneous" tests were 54 in number, used for the diagnosis of mental deficiency. This number has steadily increased until, in the New Revision of the Stanford-Binet Scale, issued by Terman and Merrill in 1937, there are two sets of 129 tests each, covering mental ages from 2 years to 22 years 10 months and providing for Intelligence Quotient values up to 170 for children and up to 152 for adults.

By correlation methods, Spearman compared the results of tests of sensory discrimination and estimates of intellectual ability, inaugurating a new phase of mathematical activity in psychology, in which, again, the tasks led to new methods. The correlation between two sets of measurements or rankings is a measure of the extent to which the sets of figures agree, and this agreement would seem to be due to a common factor in the abilities measured. It follows that "when any pair of abilities are to any extent correlated with each other, to this extent *they can be regarded as depending upon a common factor*. . . Otherwise expressed, each of the abilities may be taken to involve two factors, the one common to both, the other specific to that ability alone". Extending this thought to more than two abilities, Spearman developed his theory of two factors, and evolved various criteria for establishing the existence of the relations that fit the theory, culminating with the tetrad equation, $r_{ap}r_{bq} - r_{bp}r_{aq} = 0$, and its probable error.

VOCATIONAL TESTS

The Educable Capacity Report of 1924 gave limited approval to vocational tests, but concluded that "the range of such tests [was] not yet sufficient for any recommendation". The Medical Research Council, through the Industrial Fatigue Research it may suffer a little by comparison with its predecessor, which dealt with a more determinate theme. Perhaps, too, it was unfortunate that the first volume, concerned largely with philosophical generalities, was issued in 1906, and the second volume some two years later; for the latter bore chief witness to the solidity of the inductive treatment on which the author relied. In "Early Beliefs and their Social Influence" (1932), various essays occur that throw further light on his views about ethics, as also about religion, towards which he adopted a frankly agnostic attitude.

His latest views on this subject are to be found in "Christianity and Morals" (1939), a considerable work full of interesting material.

It remains only to say something about Westermarck's studies of the social institutions of Morocco, which country from 1898 onwards he had resolved to make his special field of first-hand investigation. Such works as "Marriage Ceremonies in Morocco" (1914), wherein he deals largely with the magical side of marriage ritual, a subject which his "History" had passed by, or "Ritual and Belief in Morocco" (1926), not to mention various minor writings, display his infinite capacity for collecting facts, conjoined with the analytic power that can reduce an apparently chaotic material to a lucid order. Indeed, Westermarck the ethnographer would bear a most distinguished name were it not that Westermarck the ethnologist had to some extent eclipsed himself. Finland may well be proud of having produced such a man, to know whom was a liberal education.

R. R. MARETT.

Prof. M. B. Krol

THE death occurred on August 6 of Prof. Mikhail Borisovich Krol, the eminent neuropathologist and director of the clinic for nervous disorders of the All-Union Institute of Experimental Medicine and of the Second Moscow Medical Institute.

Prof. Krol was born in 1879. He graduated from the medical faculty of the University of Moscow in 1901 and at first worked as assistant in the clinic for disorders of the higher nervous activities for women in Moscow under the direction of Prof. Minor, and in a number of clinics and laboratories in western Europe. In 1921 he took an active part in the foundation of the Belorussian University and of the medical faculty in Minsk. In 1924 he occupied the chair for nervous disorders in the Belorussian University, and was elected dean of the University. In 1931 he was elected a member of the Belorussian Academy of Sciences, and in 1939 became a member-correspondent of the Academy of Sciences of the U.S.S.R.

In 1932, Prof. Krol was appointed director of the chair of nervous disorders in the Second Moscow Medical Institute and director of the clinic for nervous disorders of the Institute of Higher Nervous Activities, now the All-Union Institute of Experimental Medicine. During 1934–38 he was chief physician of the Kremlin Hospital in Moscow. In 1935 he headed the Soviet delegation to the second International Neurological Congress in London. From June 1938, Prof. Krol directed the clinical section of the Institute of Experimental Medicine. He was the author of more than a hundred scientific works in Russian and other languages, among which are several monographs of first importance. He was president of the Moscow and All-Union societies of neuropathologists and psychiatrists. He was vice-president of the Medical Council of the Soviet Union, and editor of the journal *Soviet Neuropathology and Psychiatry*.

NEWS AND VIEWS

A.R.P. for Animals

THE Royal Society for the Prevention of Cruelty to Animals has issued a very useful booklet on "Animals and Air Raids" containing the A.R.P. for animals drawn up by its veterinary experts, and the demand has been so great that a second edition was immediately required. In addition to the usual veterinary treatments for burns, injuries, and gas contamination, described in a manner convenient for animal-owners at a time when only a limited number of veterinary surgeons will be available, there are some well thought-out practical hints in these difficult problems. It is stated that there are in Greater London approximately 40,000 horses, 9,000 cattle, 6,000 sheep, 18,000 pigs, 400,000 dogs, 1,500,000 cats; that there are some 200,000 working horses in England and Wales and in addition 1,004,686 agricultural horses. For horses on the streets, a halter and 12-ft. lead is advised to control the horse while unharnessing and then securing it at a spot away from falling masonry; the nosebag should be put on to keep it calm. For small dogs and domestic animals, a gas-proof air-tight box with an opening covered by a blanket dipped in a saturated solution of chloride of lime or permanganate of potash is recommended, and a similar device against gas is recommended for adapting stables, shippons and byres.

THE Government anti-gas ointment No. 1 is among the treatments recommended for mustard gas contamination of animals, and anti-gas ointment No. 2 can be smeared on vulnerable parts of a horse, as the legs below the knee and hock joints, when it has to be led through streets that may still be contaminated. The former, a powerful irritant, is composed of equal parts of stabilized bleaching powder and vaseline, the latter of chloramine *T* in a vanishing-cream base, but it is not stable. Both ointments are only for brief treatment. Petrol swabs or chloride of lime paste with frequent washes of soapy water are also recommended for contact with mustard gas that has not done serious injury, and hot water, soap and soda scrubbing for lewisite contact if blisters have not developed. The difficulties of providing for cats and birds, or of devising a gas mask for any animal, are stated to be considerable. Research is continuing in this work.

Royal Botanic Gardens, Kew

IT has been reluctantly decided to close the Royal Botanic Gardens, Kew, for the present owing to the impossibility of providing adequate air raid shelters in the Gardens. It will be readily understood that should an air raid occur and the Gardens were at all crowded with visitors, grave risks might be incurred. Not only would there be difficulty in evacuating the public before the gates were closed, but there would also be the practical impossibility of their being able to find sufficient shelter outside or means of transport to their homes. Even were it possible to provide air raid shelters, owing to the large extent of the Gardens and the six different means of entrance, the public would scarcely be likely to discover the shelters, however well labelled, at a critical moment, unless a large staff of wardens was available. Since so many of the staff have had to be detailed for guarding the Herbarium and other vulnerable spots in the Gardens, as well as the employees, there is no one who could be detailed to look after a large body of visitors. Adequate steps, it is hoped, have been taken to safeguard the collections in the Herbarium, the museums, etc., and work is proceeding so far as possible on normal lines.

The Toll of Accidents

THE Inter-Departmental Committee on the Rehabilitation of Persons Injured by Accidents has issued its final report (H.M. Stationery Office. 3*s*. 6*d*. net). The report refers to the loss to the community resulting from injuries by all classes of accidents as being "enormous", and the cost must run into many millions of pounds annually. Fractures in particular are dealt with, and the Committee recommends in the first instance concentration on the provision of fracture services, and concludes that the treatment of fractures can be satisfactorily carried out only in specially organized hospital departments. Some 15 per cent of all fractures are due to road traffic, and 29 per cent to industrial, accidents, and the Committee recommends a revision of the Road Traffic Act whereby the limits imposed on the amounts recoverable for the treatment of road accidents may be abolished. The Committee considers that every hospital with a medical school should have an organized fracture service, and that a period of training in a fracture department should be an obligatory part of medical students' training. Questions of organization and finance of fracture services are considered, and under the Workmen's Compensation Acts it is recommended, with certain reservations, that so long as the patient requires treatment by the fracture service he should continue to receive compensation as for total incapacity.

New Laboratory for Virus Research

THE Squibb Biological Laboratories, New Brunswick, New Jersey, have established a new laboratory for the study of filterable virus diseases. Dr. Raymond C. Parker, biologist of the Rockefeller Institute for Medical Research, has been appointed head of the laboratory, which will operate as a unit of the Biological Division of E. R. Squibb and Sons. The new building is a continuation of a programme of expansion which began in 1938 with the dedication to pure science of the 750,000-dollar laboratory of the Squibb Institute for Medical Research. Among the common diseases caused by filterable viruses are smallpox, rabies, equine encephalitis, measles, chicken pox, poliomyelitis, and the common cold. No specific product for the prevention of four of these diseases—the common cold, poliomyelitis, chicken pox, and measles—is yet available.

THE new virus laboratory, which was opened during a tour of the Squibb Institute and the Biological Laboratories on September 6–7, is housed in a specially constructed building, and is equipped for work with chick embryos and tissue culture, two of the techniques for work in this field. The actual working quarters consist of a large general laboratory equipped with every facility for chemical and histological work, a general preparation room for washing, drying, packing, and storing the various materials that are used, two special culture and operating rooms provided with filtered ventilation, a spacious incubator room, an animal preparation room, a bleeding room, and ample animal quarters. The arrangement of the rooms is such that the air of the culture suite proper is protected at all times from the air of the general laboratory and office quarters on one side, and of the animal rooms on the other. It is also possible for visitors to observe every step of the work in progress without entering any of the various rooms of the culture suite.

Experimentation and Disease

THE thirteenth Stephen Paget Memorial Lecture was delivered at the annual general meeting of the Research Defence Society on June 13 by Sir Edward Mellanby, who took as his subject "The Experimental Method in the Conquest of Disease" (*The Fight against Disease*, 27, Nos. 2 and 3). After a tribute to the memory of Stephen Paget, Sir Edward referred to the exhibition in an anti-vivisection office window of models of dogs suffering from rickets (incidentally, models of his own experimental animals), and remarked that it is difficult now to find throughout Great Britain children suffering from the same kind of deformity. Sir Edward Mellanby then proceeded to give instances in which the experimental method had solved the nature and causation of various diseases. In the case of facial paralysis ('Bell's palsy'), in 1844 Bell surmised on anatomical grounds that this form of paralysis was caused by paralysis of the facial nerve, and demonstrated the truth of this surmise experimentally by cutting the facial nerve in an animal and producing the condition, thus solving an age-old problem. The experimental work on the elucidation of the nature of rickets and scurvy as being due to vitamin deficiency, on the discovery of drugs curative for streptococcal infections, such as puerperal fever and pneumonia, and on the nature of cancer, were described. Finally, Sir Edward pointed out both the importance and the limits of clinical observation, and discussed some of the criticisms and failures of the experimental method.

Early Cultural Relations in Central America

AMONG communications dealing with the archæology of Central America presented to the Twenty-seventh International Congress of Americanists, which met in Mexico City on August 5–15 (see NATURE, Aug. 19, p. 319), there were several, it would appear from a preliminary report issued by Science Service of Washington, which brought forward suggestions and advanced conclusions of considerable interest in reference to the cultural relations of, and cultural successions among, the early inhabitants of Mexico and the adjacent regions. Dr. Alfonso Caso, president of the Congress, for example, in describing the results of his excavations on Monte Alban, not only argued for the common origin of the culture of that site with that of the not far distant ruined city of Mitla on the evidence of architectural affinities, but also put forward the conclusion that three stages of development are to be distinguished, which can be linked respectively with the Archaic culture of Mexico, dating from before the Christian era, the Toltec of Teotihuacan, and the Aztec. Further, Dr. A. V. Kidder, reporting on his excavations in pit-tombs near Guatemala city, assigns their builders to a period corresponding with the middle period at Monte Alban, or when the great Toltec civilization of central Mexico was approaching its decline. It would appear that the pottery from the Guatemalan pit-tombs provides a key which links the tomb builders with other early cultures of tropical central America. Some light was also thrown on the development of agriculture among the early peoples by Dr. Pablo Martínez del Rio, who advanced the theory that agriculture may have had a more rapid rise in the New World than in the Old, on the ground that differences in methods of seed selection and cultivation speeded up results for the Indian farmer, so that it was not necessary to postulate, as some botanists have done, an extremely long period of development.

Electrical Development in Iraq

IN a paper communicated to the *Electrical Review* of August 18 by W. H. Peters of Baghdad, a review is given of the post-War development of Iraq. Both Baghdad, the capital city, and Basra, its modern seaport, were left electricity systems installed by the British Army during the occupation. Being war products, they were limited in capacity and of antiquated design. During the past fifteen years these supply undertakings have been transferred to concessionaries or to the Government. The most provincial of the centre towns have shown initiative in the promotion of schemes for small plants primarily to serve the requirements of the administrative authorities for fans and for street lighting. The largest supply undertaking is that in the capital city, Baghdad, the population of which is about 250,000. It is directed by the Baghdad Light and Power Co., which is registered in the United Kingdom. It is the only supply station left which is of foreign ownership. The main thoroughfares of the city are copiously lighted, the load exceeding 300,000 watts. The port of Basra set up an efficient power station five years ago and the sale of energy in the port and the municipal area which it supplies has exceeded all expectations. The rate at which it sells power is 4½*d.* per unit for lighting and 2½*d.* per unit for domestic power.

WITHIN a year the 'Iraqi State Railway will be finally completed to the northern city of Mosul and will permit of railroad goods traffic both westwards to Syria and southwards to Basra passing en route Basra, Baghdad, Syria, Turkey and so on to Europe. This great need once fulfilled is almost certain to develop the import and export trade of Mosul, thereby increasing its prosperity. Until three years ago all the Diesel power stations were run by plant entirely of British origin, but recently German plant has made considerable headway. Iraq's exports of oil and agricultural progress show a very satisfactory increase year by year and these contribute to increased national wealth and a higher standard of living. This increase in the standard of living is not confined to the property owners and married classes, but is apparent almost everywhere. It is noteworthy that Britain has hitherto enjoyed no commercial privileges in Iraq.

Coal Utilization by Electricity

ACCORDING to the *Electrical Review* of September 1, Mr. M. Anderson, the director of the Coal Utilisation Council, estimated that to keep the public properly warm would necessitate the consumption of eight million more tons of coal per annum. To raise the standard of 'heat comfort' was one of the principal aims of the plan of campaign outlined at the last National Coal Convention. Since the success of the campaign would depend largely upon the development of the domestic and industrial demand for electric power and especially that used for 'space heating', convenience rather than necessity would be the controlling influence in regulating the demand for coal for power. Mr. Anderson referred to several other methods of increasing the coal output to compensate for the falling off in the direct demand for coal owing to the increasing use of electric power and heating in many trades. Trolley buses, also, although they have greatly diminished the demand for electric tramways and in spite of the competition of oil-engine buses, have probably increased the total demand for electric power from the public mains and consequently for coal. Trolley-buses move faster and give a much better service than almost any other vehicles. In many ways the interests of coal and its derivative electricity appear to be much the same. The demand by electric power stations on the collieries for 'slacks', 'duff' and rough 'smalls' now exceeds the supply, although coal-breaking and crushing plant has been installed at a number of collieries. This would naturally add to the cost of production.

Water-cooled Lamps for Television

A SERIOUS difficulty in television studios is the necessity of providing about double the light required by an ordinary cinema studio without subjecting the occupants and contents to intolerable heat. This difficulty has been largely overcome by the General Electric Co. of America at the television station at Schenectady, New York, by the use of a battery of four water-cooled quartz mercury arc units, containing twelve argon-filled lamps having a light output equivalent to that provided by nearly 30,000 watts of incandescent light, but they give off practically no appreciable amount of heat. According to the *Electrical Review* of August 25, the lamps are about the size of a cigarette and have an exterior of quartz. Surrounding the tube is another quartz jacket through which water passes at the rate of three quarts a minute, dispersing about 90 per cent of the heat generated. The twelve 1,000-watt lamps used have a total light output of about 800 thousand lumens, while the same wattage of incandescent lamps would provide only 330 thousand lumens. The possibility of a burn from incandescent lamps, caused by the infra-red radiation, greatly inconveniences performers who appear before the television camera. In the case of the new lamps, more than 90 per cent of the infra-red radiation is absorbed by the circulating water. The cooling system of the lamps is equipped with a pressure-operated switch and magnetic valve, since the water in the jacket must be moving before the lamp is lighted and because the lamp must be turned off automatically in the event of failure or reduction of the water supply. During operation a pressure of more than 1,000 lb. per sq. in. is developed within the quartz jacket.

Railway Electrification at Home and Abroad

ALTHOUGH the date of opening of the electrified route between Manchester and Sheffield has not yet been fixed, orders have been placed for seventy electric locomotives. This follows on the orders for eight multiple-unit trains between Manchester and Glossop. During the last two months a number of new electric services in Kent have been opened. According to the *Beama Journal* of August, the Southern Railway now possesses 3,189 electrically operated passenger vehicles, of which 603 cars have equipment designed for a maximum speed of 75 miles per hour and the remainder of 60 m.p.h. These speeds appear slow when compared with the rated speeds of Continental expresses. It must be remembered that the Southern Railway undertaking is a huge suburban network, in which high average speed is of the greatest importance. The problem of the London–Brighton railway is very different from that of the line joining Milan and Brescia. For the latter route an electric locomotive with a commercial speed of 94 m.p.h. has just been designed. In preparation for the forthcoming electrified link between Berlin and Munich, the German State Railways have accepted a locomotive with an ordinary speed of 112 m.p.h. and a possible maximum of 140 m.p.h. The use of locomotives of this type will, it is believed, reduce the journey time between Berlin and Munich from eight to five and a half hours.

Health of the Army in India during 1937

STATISTICS of the health of the British and Indian troops in India are contained in the recently issued "Annual Report of the Public Health Commissioner with the Government of India for 1937", **2** (Government of India Press, New Delhi. Rs. 2-6, or 4*s*.). The year 1937 was, from the health aspect, a good year for both British and Indian troops. There was a reduction in hospital admissions among both groups as compared with 1936 (also a good year) of 14·3 per 1,000 of strength among British troops, and 37·0 among Indian troops. Although the admission ratio appears to be on the downward trend, conditions cannot be considered satisfactory according to modern health standards so long as 568 out of every 1,000 British soldiers and 390 out of every 1,000 Indian soldiers are admitted to hospital during the course of a year. Compared with the troops in the United Kingdom, the hospital admission ratio in India is almost exactly double. The reasons are partly climatic, and partly due to the more primitive methods of sanitation, both in the army and among the civil populations in contact with it. There has been, however, a reduction in incidence of such diseases as malaria and the enteric groups of fevers. A new synthetic drug named 'Certuna' has given promising results in the treatment of sub-tertian malaria. Information is given of the work being done to supply pure water to the stations, on conservancy systems, and on the sanitary control of milk and foods.

Work of Indian Medical Institutes

THE reports of the Haffkine Institute for 1938 and of the Pasteur Institute of India, Kasauli, for 1937, have reached us. The Haffkine Institute is the centre for the preparation of Haffkine's preventive plague vaccine, of which 1,137,086 doses were issued during the year. Some trials of the Institute's anti-plague serum were made in a small outbreak of plague, with a mortality of about 26 per cent, compared with a mortality of about 63 per cent with other non-specific treatments. Two of the sulphanilamide drugs, Prontosil and M. and B. 693, so valuable in streptococcal infections, were tried in plague but showed little or no curative power. A number of research studies on plague vaccine and serum, anti-malaria drugs, human and rat leprosy, fleas, and other subjects are summarized. At the Kasauli Pasteur Institute, anti-rabic treatment is carried out. The total number of patients attending the Institute and its centres was 28,076, of whom

20,936 received the full course of anti-rabic treatment, with a mortality of 0·45 per cent. The vaccine employed was a carbolized 5 per cent emulsion of brain of sheep inoculated with Paris fixed virus. The deaths from rabies registered in 1937 in the Punjab and the United Provinces numbered 438.

Cosmic Data

Two valuable summaries of the data at present available as to the motion of the galactic system among the nebulæ and as to the sources of stellar energy are contributed by Dr. E. Hubble, of the Mount Wilson Observatory, Pasadena, and by Prof. H. N. Russell, director of the Princeton University Observatory respectively, to the August issue of the *Journal of the Franklin Institute*. With respect to the extragalactic nebulæ taken as frame of reference, the galactic system is moving with a speed of the order of 100–200 kilometres per second in the direction of the northern galactic latitudes. The sun is rotating about the centre of the galaxy with a speed of the order of 275 kilometres per second in the galactic direction latitude 0°, longitude 55°. The resultant is a speed of the order 300 kilometres per second in the direction latitude 35° north, longitude 55°. After pointing out that the reactions which provide the stars with their energy must be accompanied by a loss of mass, Prof. Russell summarizes the recent work of Prof. H. A. Bethe, of Cornell University, on the six steps by which the impact of four protons, that is, hydrogen atoms, on a carbon atom which acts as a catalyst lead to the production of a helium atom. Owing to the diminution of mass involved in the conversion, the process is capable of supplying the sun's energy if its temperature is of the order 18–21 million degrees centigrade, that of Sirius at 22 million and that of γ Cygni at 30 million, all of which temperatures are in agreement with astrophysical observations.

The National Central Library

THE twenty-third annual report of the Executive Committee of the National Central Library refers to the way in which development has been hampered by the absence of sufficient funds. The only department which is able to provide anything like an adequate service is the Bureau of American Bibliography, recently established with the aid of a generous grant from the Rockefeller Foundation. The two main sources of income have been, as in previous years, the grants of £5,000 from the Treasury and £4,000 from the Carnegie United Kingdom Trust. Of the 10,825 volumes added to the library, 7,203 were presented; 46,715 books were issued to libraries and 11,968 to adult classes. The total number of outlier libraries is 135, consisting of 113 special libraries, 19 London borough libraries and 3 urban libraries, representing a stock of 4,201,000 volumes, from which 11,361 books were lent during the year. The regional library systems now cover the whole of England and Wales, embracing 479 libraries. During the year, 50,031 books were lent by libraries in regional systems to other libraries in their own system, and in addition 7,104 books were lent to libraries outside their own regional area through the National Central Library. Of the 3,538 books lent to university libraries, 1,846 were supplied by the National Central Library and its outliers, 1,536 by other university libraries, and 156 by foreign libraries. As against 508 books lent to libraries in 24 foreign countries, libraries in 16 foreign countries lent 283 books to libraries in the British Isles.

Data of Seismology

VALUABLE seismological data have just been received from India (Government of India, Meteorological Department, Seismological Bulletin, July–Sept. 1938). This publication contains readings of the seismograms received at the observatories of Agra, Bombay, Calcutta, Colombo, Dehra Dun, Hyderabad and Kodaikanal, together with non-instrumental reports. Readings from the Indian observatories are particularly important for the determination of the epicentres of earthquakes removed from North America, Europe and Japan, where the majority of the earth's seismological stations are situated. The non-instrumental reports indicate the occurrence of four local shocks in July, seven in August and six in September, some of which were followed by aftershocks. Silchar, Lahore and Kalat each reported shocks on two separate occasions.

Earthquakes during June 1939

ACCORDING to the Central Seismological Bureau at Strasbourg, 132 earthquakes were registered by seismographs or felt by people during June 1939. The most on any one day was ten on June 4, and the least on any one day was one on June 25. Undoubtedly the strongest shock during June was that of June 22 on the Gold Coast, having an epicentre provisionally calculated to be 5·7° N., 0·7° W. The next three in intensity were June 18, felt scale 7 (Rossi-Forel) at Costa Rica, June 5 with epicentre in the Atlantic west of the Azores, and June 8 with possible deep focus (130 km.) in the Islands of Samoa. Other shocks for which provisional epicentres could be obtained were June 3, Tananarive (scale 2); June 4, north-west Australia and Arizona; June 6, Algeria; June 12, Porto Rico; June 23, near Apia; June 24, two in California; June 27, Philippines; and June 29, Vrancea. During June the Fort de France station registered eight local tremors.

New Fellows in Pure Research at Mellon Institute

DR. R. S. Tipson and Dr. Warner Carlson have been appointed fellows in the Department of Research in Pure Chemistry in the Mellon Institute. Dr. Tipson was born in Derbyshire in 1906. He was awarded the degree of B.Sc. of the University of Birmingham in 1927 and then engaged in research on the carbohydrates under Prof. W. N. Haworth. Later he conducted an investigation, for the British Empire Cancer Campaign, on the preparation of tobacco tar and determination of its constituents. In 1929 he was appointed to a research fellowship in the department of industrial and cellulose chemistry, McGill University, Montreal, Canada, where, in collaboration with Prof. Harold Hibbert, he examined the structure of certain bacterial polysaccharides. He went to the United States in 1930 to become a research assistant to Dr. P. A. Levene on the staff of the Rockefeller Institute for Medical Research, New York, and in 1926 was promoted to the position of research associate. Dr. Carlson was born in Lincoln, Nebraska, in 1913. He pursued his early professional education at the University of Nebraska, from which he obtained the degree of B.S. in chemistry in 1933 and the degree of M.S. in the same field in 1935. A little more than a year was spent at the Iowa State College in biophysical chemistry, after which he transferred to the Ohio State University. At the latter institution he held a research fellowship in the Industrial Research Foundation, receiving the degree of Ph.D. in March 1939 with a thesis entitled "Physiological Studies on the Synthesis of Dextran by Bacteria of the Genus Leuconostoc".

Mathematical Tables

THE Works Progress Administration of the City of New York is undertaking extensive computation of mathematical tables. The work is sponsored by Dr. L. J. Briggs, director of the National Bureau of Standards, and is intended to give employment to clerical workers in New York. Several tables, including Bessel functions for complex arguments, exponential and trigonometric integrals, and the error function are completed or in active progress. Of the tables under consideration, the most noteworthy is a table of elliptic functions for complex arguments so designed as to cover a period parallelogram in each case.

Recent Sunspots

Two very large groups of sunspots have recently appeared. The first of these was a big single spot with companions increasing in size; the second group comprised a complex stream. Positions and areas are as follows:

Date on disk	Central meridian passage	Latitude	Maximum area
Aug. 26—Sept. 7	Sept. 1·0	15° S	3000
Sept 4—Sept. 17	Sept 10.5	15° S	2500

The areas are corrected for foreshortening and are expressed in millionths of the sun's visible hemisphere. An extensive bright eruption associated with the second group was observed at Greenwich on September 8 from 11h. 35m. until about 12h. 30m., the maximum being at 11h. 43m. U.T.

Announcements

THE printed addresses prepared in connexion with the Dundee meeting of the British Association, which include the presidential address by Sir Albert Seward, the addresses of sectional presidents, the first British and American Association Lecture, by Dr. Isaiah Bowman, on "Science and Social Pioneering", and Sir Richard Gregory's address as chairman of the Division for the Social and International Relations of Science entitled "Contacts of Religion and Science", can be obtained, temporarily, from the British Association, Down House, Downe, Farnborough, Kent, price 6*d*. each.

OWING to the outbreak of war, it has been necessary to postpone indefinitely the general discussion arranged by the Faraday Society on "The Electric Double Layer", which was to have been held September 25–27. It is at present hoped to publish the papers in an early issue of the *Transactions*.

THE National Emergency Blood Transfusion Service announces that registered blood donors in London and Greater London will be notified when they are required, and until then they need take no action. Donors having group *O* blood will be called upon first for blood to be stored for national use.

THE Joint Tuberculosis Council will hold a course in radiology at Shire Hall, Castle Hill, Cambridge, during September 20–22. A course in the diagnosis and treatment of pulmonary tuberculosis will be held at the Tuberculosis Office, 352 Oxford Street, Manchester, during October 10–14. Further information can be obtained from Dr. J. B. McDougall, Preston Hall, near Maidstone.

PROF. ALBRECHT SCHMIDT of Frankfort-on-Main and Prof. Johannes Stark, of the Physikalisch-Technischen Reichsanstalt, Berlin-Charlottenburg, have been awarded the Goethe Medal for Art and Science, and Dr. Karl Frik, director of the Werner Siemens Institute for Radiology in the Robert Koch Hospital in Berlin, has been awarded the Rieder Medal by the German Röntgen Society.

DR. GEORGE W. CORNER, professor of anatomy, University of Rochester School of Medicine, New York, has been appointed editor of the *American Journal of Anatomy* in succession to the late Dr. Charles R. Stockard.

THE issue of the *Medical Journal of Australia* for July 1 is a silver jubilee number containing articles on the progress of medicine, surgery, preventive medicine and medical journalism during the last twenty-five years.

AN institute for research in rural hygiene has recently been set up in a farmhouse at Lichtenstein in Bavaria, the birthplace of Max von Pettenkofer, the founder of experimental hygiene in Germany.

THE seventh International Congress on Rheumatism will be held in New York, Philadelphia and Boston during June 1–10, 1940. Further information can be obtained from the Ligue internationale contre le rhumatisme, Keizergracht 489, Amsterdam.

ACCORDING to official statistics, the population of Japan on October 1, 1938, was 72,227,700, or 969,000 more than in the previous year. Tokyo is the most populous city with 6,457,000 inhabitants.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 517.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Quantitative Comparison of the Biological Effects of Neutrons and other Ionizing Radiations

A CONSIDERABLE number of tissues have been exposed to very high energy Be-D neutrons ($\sim$ 12 Mev.) with the help of cyclotrons, in the United States. The published values of the ratio γ/N of the gamma-ray to the neutron doses for a given biological effect range from 2 to 8. These ratios should be comparable among themselves, but since the neutron doses were measured in arbitrary units they cannot, without further experiment, be regarded as indicating the ratio of the absorbed neutron and gamma-ray energy. Two investigations have been reported in which an attempt has been made to measure this quantity. Zimmer[1], using Li-D neutrons, found the ratio of gamma-ray to neutron energy necessary to produce the same increase in mutation rate in Drosophila sperm to be $\gamma/N' = 0{\cdot}7$, whereas for the lethal effect on the bean root we[2] have found $\gamma/N = 11$. Comparable procedures were adopted for the estimation of the neutron energy absorbed in the tissue in the two cases, and these were roughly checked by the exchange of ionization chambers[3].

Before attempting any biological interpretation of such a striking difference in the sensitivity of bean roots to gamma-rays and neutrons we have considered whether any known physical process could increase the energy absorption of a given beam of neutrons in tissue appreciably above the value which we have estimated. This value takes into account the recoil atoms of hydrogen, carbon, oxygen, and nitrogen, which contribute respectively 92 per cent, 1·7 per cent, 5·2 per cent, and 0·4 per cent of the total estimated energy absorption, and the disintegration of nitrogen, which adds a further 0·4 per cent. The interaction of fast neutrons with nearly forty elements has been measured by various authors[4], including all elements, other than the inert gases, up to and including calcium. The energy absorbed per unit mass of the element by the process of nuclear recoil is maximum for hydrogen, and falls steadily to 1 per cent of this value for calcium, and 0·05 per cent for lead. In some cases, for example lithium, a single atomic disintegration together with the subsequent decay of the unstable nucleus, may liberate more than ten times as much energy as that of the average recoil hydrogen atom. Such atoms, however, are present in tissue in altogether too small amounts to make an appreciable contribution to the total energy absorption, and a careful study of the data makes it fairly certain that in the case of irradiation by D-D neutrons no atomic disintegration or induced radioactivity is likely to make a larger contribution than that estimated above for nitrogen.

Lest any of the minor atomic constituents of protoplasm had been overlooked, the matter was tested experimentally. Grass tips were incinerated with nitric acid so as to obtain a fifteen-fold concentration of the non-volatile constituents. This ash was strongly irradiated for thirty minutes and tested (*a*) by insertion into a large ionization chamber connected to a Lindemann electrometer, (*b*) by a Geiger counter, for induced radioactivity. Measurements were commenced 30 sec. after the end of the irradiation. Method (*b*) showed some radioactivity. By introducing uranium into the position occupied by the ash it was possible to estimate the energy liberation in tissue corresponding to any given observed activity and decay constant. This made it clear that there was no element of period greater than $\sim$ 3 sec. present in the irradiated ash which, either during irradiation or the subsequent five days*, could make any appreciable contribution to the energy absorption in this tissue. To test for short-period activity the ash was applied as a thin layer to the inside of a small electron metal ionization chamber, with 15 per cent by weight of dextrin as a binder. When irradiated, the difference between the observed ionization and that to be expected from the chamber plus dextrin represented only 7 per cent of the total energy absorption in tissue.

We are thus unable to find any reason for supposing that our estimates of neutron energy absorption in tissue are seriously in error. Probably the explanation of the greatly increased sensitivity of certain tissues to neutron, as compared with gamma-ray energy, must be sought in terms of specific relationships between the distribution of ionization and biological structure. It is very desirable, however, first to know whether neutron and gamma-ray energy are equally efficient in producing simple chemical changes, and this we are in process of investigating.

We gratefully acknowledge the financial assistance of the British Empire Cancer Campaign.

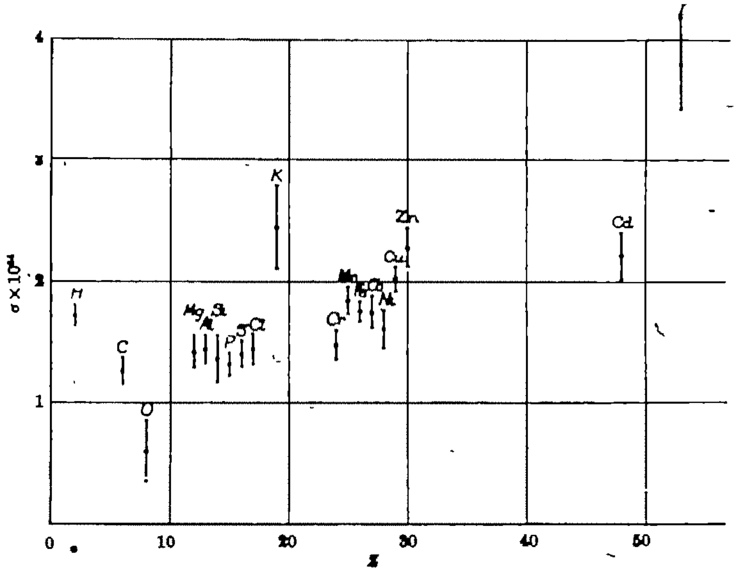
Scattering of D—D Neutrons

EXPERIMENTS hitherto performed on the scattering cross-sections of various substances for D—D neutrons have led to fundamentally different results. Most observers have found that the cross-section σ increases regularly with the atomic number, and some have deduced from their results the variation with Z of ξ, the 'sticking factor'. Kikuchi and Aoki and collaborators[1], however, have observed a periodic variation of σ with Z. The detectors used in all these experiments have been either sensitive to fast neutrons of wide range of energy, or sensitive to slow neutrons. Since the 170 min. period of phosphorus is excited only by neutrons of energy greater than about 2 Mev., it is an ideal detector for D—D neutrons, especially as our experiments have shown that there is no observable elastic scattering of these neutrons by elements of widely differing atomic number such as sulphur, iron and lead. The disadvantage of the use of phosphorus, however, lies in its relatively low intensity of excitation, so that the detector had to be placed near (9 cm.) the target. In consequence the geometry was not ideal, and only relative cross-sections could be obtained. In spite of this, however, the mean free path in paraffin wax was the same to within experimental error as that observed by Booth and Hurst[2], among others, using better geometry and an indium foil as a slow neutron detector.



This result is the more curious in view of the fact that for the majority of the elements investigated the cross-section observed was roughly half of the value obtained by previous observers. While our results vary in accuracy between 5 and 15 per cent, the fine structure observed by Kikuchi and Aoki is roughly corroborated. A graph showing variation of σ with Z (so far as iodine) is given.

A fuller account of the experiments performed will be published elsewhere.

Selective Oxidation of Aluminium Alloys

The superficial film formed on heating an alloy in air consists usually of a mixture of oxides of the alloying metals. In some circumstances, however, the oxide of only one of the elements—often of a minor constituent—appears on the surface. This has been known for some time to be the case with oxidized surfaces of brass and stainless steels. Electron-diffraction investigations have lately furnished a considerable number of similar examples[1–4].

Experiments with some aluminium alloys have shown that selective oxidation in these alloys occurs with a hitherto unrecorded prominence. The alloys in question were aluminium-beryllium and aluminium-magnesium, they were oxidized in an electric furnace, in air at atmospheric pressure. The composition of the surface layers after oxidation was investigated with the aid of an electron-diffraction apparatus.

A 99·8 per cent aluminium 0·2 per cent beryllium alloy oxidized at 630° C. gave the electron-diffraction pattern of BeO; at lower temperatures the well-known diffuse Al_2O_3 pattern was recorded. So small an admixture of beryllium is thus sufficient to cause a layer of pure BeO to form on the surface, provided that the alloy is oxidized at a sufficiently high temperature. For an alloy containing 3 per cent of beryllium, the limiting temperature was 500° C. on surfaces oxidized at 500° C. and higher, BeO only appeared on the surface.

The selective character of oxidation of the surface of aluminium-magnesium alloys has already been recorded[1]. Preston and Bircumshaw found that MgO is formed on the surface of an alloy containing so little as 0·5 per cent magnesium. We were successful in extending this limit by producing a film of MgO on an alloy containing no more than 0·03 per cent of magnesium. The indispensable condition was to perform the oxidation just below the melting point of the alloy. The specimen was kept for twelve hours in a furnace where the temperature was maintained between 650° and 660° C. In the case of an alloy containing 0·1 per cent magnesium, an oxidation temperature of 620° C. was sufficient. With a 1·4 per cent magnesium alloy the surface layers consisted of MgO at 400° C.

In looking for an explanation of such striking facts as the formation of a layer of pure MgO on the surface of an alloy containing barely one atom of magnesium for about 3,000 atoms of aluminium, chemical arguments are of little help. As a matter of fact, the heat of oxidation of aluminium (namely, 190) is much greater than that of magnesium (143) or beryllium (131). 'Preferential' oxidation in the sense of greater chemical affinity of magnesium or beryllium for oxygen, or reduction of the previously formed Al_2O_3 by beryllium or magnesium, can thus scarcely be considered as a probable hypothesis.

The accumulation of ZnO on the surface of brass has been attributed by some investigators to the higher vapour pressure of zinc. The same might have played some part in aluminium-magnesium alloys. Beryllium, however, possesses a much higher boiling point than aluminium. Thus it would be expected that aluminium would have a higher vapour pressure at the temperatures at which oxidations were performed. Accumulation of BeO in surface layers cannot be explained, therefore, in this way either.

One of us has pointed out the important role of the surface tension of the constituents of an alloy in determining the composition of its surface layers[3]. Unfortunately, there are no data with regard to the surface tension of the three metals involved in these investigations. This makes it impossible to predict which of the metals should be adsorbed on the surface. If we assume, however, that the difference of surface tensions is the cause of highly selective oxidation of aluminium-beryllium and aluminium-magnesium alloys, it is to be inferred that the surface tension of magnesium and beryllium is much lower than that of aluminium.

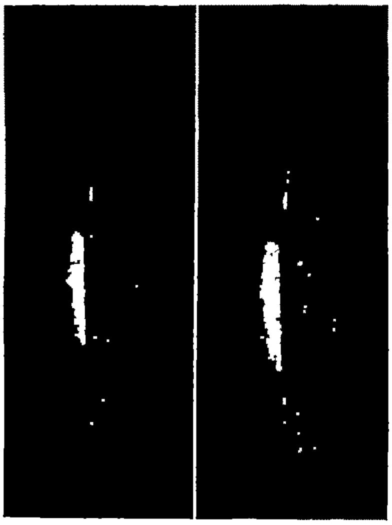
Extremely Bright Spots on Coolidge Tube Target

WHILE making tests with a newly made Coolidge tube with molybdenum target, we discovered several bright spots of unusual brightness on its target surface.



(*a*) (*b*)

The accompanying illustration shows (*a*) photographs of the target when only the cathode of the Coolidge tube was heated, that is, while the X-rays were not being radiated, and (*b*) of the same target taken when a voltage of 50-cycle 40 kv. (peak value) was impressed on the anti-cathode and an electronic current of 20 mA. D.C. was flowing, that is, while X-rays were being radiated. In front of the lens of the camera, a right-angled glass prism was attached so as to prevent the X-rays being projected on the sensitized plate of the camera. In (*b*) several white spots will be seen, whereas in (*a*) no such spots exist. The photograph does not show these spots well; the actual bright spots glare quite intensely and look as if they were embossed on the target surface. The target of the Coolidge tube was continuously cooled with running water.

In order to ascertain whether these bright spots were produced during the half-cycle in which the electronic current follows, or during the other half-cycle, a stroboscopic observation was made, and it was found that they were produced only during the former half-cycle, and the larger the instantaneous value of current the greater the intensity. Furthermore, when the heating current of the cathode was kept constant, there was practically no change in the brightness of the spots, even when the anode voltage was lowered to a voltage such as 10 kv. (peak value), at which no radiation of the characteristic X-rays of molybdenum would take place; but when the heating current was varied, the brightness was greatly affected, these spots being nearly invisible when the electronic current was less than 10 mA.

From these results it would appear that the spots are due to electronic bombardment; in other words, due to a particularly intensified electric field at some minute protrusions accidentally existing on the target surface, the protruding points become incandescent. As clearly seen from the photographs, the surface of the target is not perfectly smooth; it is covered with scratches, as if the surface had been brushed over. These facts support the view put forward.

I. KOGA.
M. TATIBANA.

Department of Electrical Engineering,
Tokyo University of Engineering,
Tokyo.
June 19.

A SIMILAR phenomenon to that described by Messrs. Koga and Tatibana has been observed during the course of certain research work on multi-segment magnetrons operating under rather abnormal circuit arrangements at about 80 cm. wave-length.

Brilliant points of luminescence have been observed on the rear surfaces of the anode segments, which are each in the form of a hollow tantalum triangle with one curved face receiving the electron stream, and generally running very hot, about yellow-white. The appearance of these spots of light was so distinctive that it was at first thought that holes had been formed in the anode rear surface, making visible the almost white-hot inner face. On examination, when not operating, it was seen that the anodes were not punctured, nor was it possible to account for such puncturing, although a 'cyclotron' effect has been observed giving a charge on a screen surrounding the anodes four times the voltage applied to the anodes.

It was found that a high output was needed before the spots appeared and the general order was about 400 watts radio frequency with the anodes dissipating about 175 watts. Furthermore, the spots were critical with regard to filament emission and also disappeared suddenly below 2,100 volts on the anodes, but were quite unchanged by large variations of voltage above this: a fact which is noticed by the Japanese investigators.

I remember noting several years ago similar effects in a Farnsworth cold cathode multiplier (photo-electric cathodes with focusing magnetic field) where flash-overs kept occurring, maybe due to the liberation of gas from an almost microscopic incandescent protuberance.

Vitamin B_6 and Skin Lesions in Rats

VITAMIN B_6[1] has been defined[2] as "that part of the vitamin B_2 complex which is responsible for the cure of the specific dermatitis developed by young rats fed on a vitamin B-free diet supplemented with purified vitamin B_1 and lactoflavin" (riboflavin). The specific skin lesions ("rat acrodynia") are characterized by symmetrical dermatitis with œdematous, scaly skin, mainly on the most peripheral parts of the body, such as the mouth, nose, paws, ears and tail.

In a later study, Lepkovsky, Jukes and Krause[3] have shown that rats need a further factor, in addition to vitamin B_1, riboflavin and vitamin B_6, to supply the requirements for normal growth and development on a diet deficient in vitamin B. In the opinion of the authors mentioned, this additional factor corresponds presumably to the so-called chicken pellagra factor or the "filtrate factor"[4]. Addition of vitamin B_6 (called [3] also Factor 1) alone did not permit growth in rats, and "some of the rats developed swollen eyelids which tended to stick together. The eyes were watery and the nose was inflamed"[3]. Addition of the filtrate factor (called also Factor 2) alone resulted in slow growth, and the rats developed the specific acrodynia-like skin condition. Addition of both Factor 1 and Factor 2 assured normal growth and development.

Apart from the sticky eyes and sore nose, the skin lesions were not attributed to deficiency of the filtrate factor but almost exclusively to that of vitamin B_6, which was regarded as the specific skin factor of the vitamin B_2 complex for rats, the skin lesions in riboflavin deficiency in rats being less conspicuous. Thus, the designation *adermin* has been proposed by Kuhn and Wendt[5] for vitamin B_6.

In a preliminary paper[6], attention has been directed to the fact that this conception was not borne out by direct experiments in which pure vitamin B_6 was substituted for the crude vitamin B_6 concentrate used by Lepkovsky, Jukes and Krause[3]. Admittedly, in rats suffering from acrodynia (with the exception of a few refractory rats), addition of 10 micrograms daily of vitamin B_6, natural or synthetic*, brought about improvement of the specific dermatitis and in many instances led to complete cure. In the further course of these experiments, rats often died from other internal deficiency diseases, such as panmyelophthisis, adrenal hæmorrhage, liver injury and kidney injury, the nature of which need not be discussed here. Later, in a large percentage of the remaining group of rats, there developed extreme and severe skin lesions which differed from those seen in acrodynia in rats. Three more or less distinct types of lesions were observed in this group of rats, which to date includes more than 100 animals.

Type I. The hair over the abdomen is matted together, appears damp and is sticky to the touch. There is loss of hair around the chin, nose and eyes and over the forehead between the ears. The sides of the cheeks and also the abdomen are often covered with scales, which are generally brown in colour. These scales may sometimes become quite thick. In advanced cases, the lids of the eyes seem to be inflamed and are sometimes kept closed, while the brown scaliness may extend over the sides of the forehead. Probably on account of irritation, the animals often rub the forehead and cheeks with the forepaws and thus transfer a coating of the brown scaly matter to the paws. There is emaciation and manition.

Type II. After complete cure of the acrodynia, new lesions start around the mouth, the groin and the axillæ, in the form of inflammation and scale production. Later, alopecia follows, extending to the neck and over the back. Hyperæmia may be seen also on the ears, and the forepaws often become excoriated. In several animals generalized scaliness (exfoliative dermatitis) has been observed.

Type III, the rarest in our observation, corresponds to the descriptions given[4,7] of rats with watery eyes which stick together and sore mouth.

Concentrates of liver and yeast and filtrates from wheat germ, yeast and rice polishings, after adsorption on fuller's earth, in proper doses assure complete cure of all these skin manifestations.

In view of these results, the part played by the vitamin B_2 complex in dermatologic conditions has to be extended beyond vitamin B_6, and the term *adermin*, because it is misleading, should be abandoned. In accordance with the chemical nature of vitamin B_6, which is a pyridine derivative containing several oxy (methoxy) groups, the term *pyridoxin* appears to be appropriate.

Influence of Glutamine on the Growth of *Streptococcus hæmolyticus*

IT has been recently demonstrated by McIlwain, Fildes, Gladstone and Knight[1] that glutamine is an essential growth factor for most strains of hæmolytic streptococci freshly isolated from pathological processes. By the use of glutamine, these investigators have been able to replace completely the hitherto essential meat extractives in their culture medium.

We have been able to confirm the work of McIlwain and his co-workers. Employing a strain of *Streptococcus hæmolyticus* isolated from a case of septicæmia which terminated fatally, good growth was obtained in a peptone base medium, similar to that used by McIlwain *et al.*, when it was supplemented with glutamine. Controls showed little or no growth. The specimen of glutamine used was prepared from natural sources by the method of Vickery, Pucher and Clark[2]. Under similar test conditions, glutamine exhibited a moderate growth-stimulating effect on several stock cultures of *Str. hæmolyticus*.

It is of considerable interest to recall the observations of Dart[3], who showed that beet juice contains a powerful growth-stimulating hormone for *Str. hæmolyticus*. He was able to demonstrate a marked reduction in the 'lag phase' during the growth of this bacterium in beef infusion broth to which had been added 0·1 per cent beet juice. Since beets are a rich natural source of glutamine, the connexion is suggestive.

In an attempt to grow the freshly isolated strain of *Str. hæmolyticus* in a medium of completely defined chemical composition, including glutamine, the peptone in McIlwain's medium was replaced with an amino-acid mixture (Fildes[4]) frequently used in this laboratory for nutritional studies. No growth was obtained under these conditions, nor was growth observed when the peptone was replaced with acid-hydrolysed casein. In view of these findings, it seems likely that there is present in peptone another factor (or factors) which must be available before freshly isolated strains of *Str. hæmolyticus* can be cultivated in a medium of known chemical composition.

Nature of a Group in Papain Essential to its Activity*

MUCH of the literature on the activation and inactivation of papain[1,2,3,4] supports the hypothesis that there is an essential SH group in the active enzyme.

The active crystalline enzyme[5], however, does not give a positive nitroprusside test or a satisfactory titration with porphyrindin[6]. Crystalline papain, like certain other proteins, was observed to give a positive nitroprusside test in the absence of cyanide only after denaturation. If, however, the native protein was first inactivated with iodoacetate, then separated from the excess of iodoacetate by precipitation with salt and finally denatured as before, no nitroprusside test without cyanide was obtained. In agreement with this observation, hydriodic acid was detected in the mother liquor from the salt precipitation. Titration of the denatured protein in urea solution by iodine gave results which indicate that only one sulphur group (of about ten in the papain molecule) is involved and that it disappears when the enzyme is inactivated by iodoacetate or cystine. This is supported by the observation that inhibition of papain activity is produced by one molecular equivalent of iodoacetate. Papain is still 'native' after reaction with cystine; that is, the solubility is apparently unaltered and the protein can still be crystallized.

It may be concluded that the SH group that appears on denaturation is blocked from reaction with some but not with all reagents while the protein is in the native state. Dr. M. L. Anson informed us by private communication that he has observed that SH groups in certain proteins react with iodoacetamide, but are not attacked by oxidizing agents.

Results of titrating denatured papain SH groups with iodine are shown in the accompanying table:

Enzyme preparation	Treatment of protein	Equivalents of protein × 10^7		Equivalents of sulphydryl × 10^7	SH per equivalent of active protein
		Total	Active		
A	None	37	30	28	0·93
A	Iodoacetate	37	2	5	—
A	None	19	15	17	1·13
A	Iodoacetate	19	1	1	—
B	None	32	23	27	1 17
B	Cystine	32	10	11	1·1
B	Cystine	31	7·3	11	1·5
B	Iodoacetate	31	1	2	—

The equivalents of protein are calculated using a molecular weight of 30,000[7]. The enzyme preparation treated with iodoacetate contained 21 milk clotting[7] units of papain per mgm. of protein nitrogen when activated with cyanide, and the one treated with both cystine and iodoacetate contained 27 units.

After the native protein had been freed of the 5–10 fold excess of iodoacetate or the excess of solid cystine, it was denatured by heating at 70–75° C. for 10 minutes. The protein was centrifuged out, washed and finally dissolved in strong urea solution. This solution was treated essentially by the method described by Lavine[8] for the estimation of cystine except that the temperature was 0–5° C. The sodium thiosulphate solution was 0·01 *N*. The blanks agreed to within 0·02 ml.

Glutamic Acid as a Hydrogen Carrier in Animal Tissues

IT has previously been shown that α-ketonic acids liberate carbon dioxide when added to animal tissues under anaerobic conditions[1]. The evolution of carbon dioxide was found to be due to a 'dismutation'.

$$(1)\quad 2\,\mathrm{R.CO.COOH + H_2O = R.CH(OH).COOH + R.COOH + CO_2.}$$

We have now found that the anaerobic carbon dioxide formation from α-ketoglutaric acid in kidney and in heart muscle is greatly increased by the addition of ammonium chloride. The analysis of this effect showed that α-ketoglutaric acid 'dismutes' with α-iminoglutaric acid (which arises on addition of ammonium salt to α-ketoglutaric acid)[2] as follows:

$$(2)\quad \underset{(\alpha\text{-ketoglutaric acid})}{\mathrm{COOH \cdot (CH_2)_2 \cdot CO \cdot COOH}} + \underset{\alpha\text{-iminoglutaric acid)}}{\mathrm{COOH \cdot (CH_2)_2 \cdot CH : (NH)\;\; COOH}} + \mathrm{H_2O}$$
$$= \underset{(\text{glutamic acid})}{\mathrm{COOH \cdot (CH_2)_2 \cdot CH(NH_2) \cdot COOH}} + \underset{(\text{succinic acid}).}{\mathrm{COOH \cdot (CH_2)_2 \cdot COOH}} + \mathrm{CO_2}$$

For example, 17·9 mgm. sliced kidney cortex (rat) produced in 140 minutes in the presence of

0·02 *M*. α-ketoglutarate 0·02 *N*. ammonium chloride	0·02 *M*. α-ketoglutarate	
327	136	μl carbon dioxide
222	80	μl succinic acid
234	81	μl glutamic acid

In the presence of molecular oxygen reaction (2) is followed by reaction (3).

$$(3)\ \text{glutamic acid} + \tfrac{1}{2}O_2 = \alpha\text{-ketoglutaric acid} + NH_3;$$

and the net result of (2) and (3) is the oxidation of ketoglutaric acid to succinic acid and carbon dioxide:

$$COOH.CH_2.CH_2.CO.COOH + \tfrac{1}{2}O_2 = COOH.CH_2.CH_2.COOH + CO_2$$

The system

$$\text{glutamic acid} \rightleftarrows \alpha\text{-iminoglutaric acid}$$

thus acts as a hydrogen carrier in the oxidation of α-ketoglutaric acid. It has been known for some time that, in kidney, ammonium salts increase the rate of oxidation of α-ketoglutaric acid and of those substances which may give rise to the intermediary formation of α-ketoglutaric acid, namely, glucose, lactic acid and pyruvic acid[3,4]. This may now be explained by the fact that ammonia, according to reaction (2), is required in the oxidation of ketoglutaric acid.

Reaction (2) was not observed in liver, pigeon brain or pigeon breast muscle. Several facts suggest, however, that glutamic acid (or glutamine) acts as a hydrogen carrier in these tissues also, but it is not yet clear from which substrates the hydrogen is accepted. Isocitric acid[5] and β-hydroxybutyric acid[6] which may donate hydrogen to iminoglutaric acid in artificial enzyme systems do not appear to react in the intact cells.

Tarsiers in Captivity

SPECTRAL tarsiers have been maintained in captivity for varying lengths of time by a number of observers[1,2,3]; but only at stations actually within the area of their geographical distribution (Melanesia). No record has been found of this form reaching the zoological gardens of Europe or North America.

The present note relates to a pair of tarsiers that have been held under laboratory conditions at New Haven, Connecticut, for the past nine months. These specimens, a mature female and her presumptive offspring, a young male, were captured by Mr. J. S. Eckman at Barrio Bad-As, Province of Surigao, N.E. Mindanao, Philippine Islands, in July 1938. Mr. Eckman kept them as pets until October 1938 when, coming to the United States, he brought them at our request to Los Angeles, California, arriving in mid-November. From there they were at once shipped by air to New York, and were received at New Haven on November 18, 1938.

These animals have thriven in captivity, in spite of a somewhat less than ideal environment. During the winter the temperature of their room executed fluctuations ranging from 24° to 30° C., although we sought to maintain an average of 28° C. A crude humidifier was only partially successful. They are kept in a basement room with a north-western exposure, receive no sunlight, and only a low intensity of light. They have received, however, about 3 hours light every other day from a 'Sperti' ultra-violet lamp.

The only food which they have accepted with absolute consistency has been mealworms (Tenebrio larvæ), of which they have taken some 50–60 each per day. To a dish of this food have been added, every day or so, a little salt mixture and a few drops of cod liver oil. New-born mice were eaten, two or three a day each, for the first few weeks that we had the tarsiers; but these are now always refused. Nor will they touch raw beef or liver since becoming accustomed to the live food, and both fruit and milk are always rejected. The weight of the female increased rapidly from 164 gm. to a maximum of around 208 gm.; this probably represents weight regained plus certain fat deposition. The weight of the male has increased more steadily from 106 to 159 gm., most of which increase would appear to represent growth.

The tarsiers are kept in a large cage containing a smaller 'hide-out' cage to which they keep for the greater part of the day, and to which they rapidly retreat when frightened. They emerge around 6 p.m. and are feeding and very active until at least 4 a.m. Their reaction to the ultra-violet light is quite capricious; sometimes they come out and bask within a foot of it, at other times they seek to remain hidden.

The female has been observed to exhibit cyclical swelling of the external genitalia, coupled with a dramatic change in the cellular content of the vagina from the normal mixture of leucocytes and nucleated epithelial cells to complete or almost complete cornification of the epithelials with partial or complete disappearance of leucocytes. The times between the estimated peaks of these cycles have ranged from 23 to 28 days over six such cycles. A sufficiently intensive search for red blood cells in the vaginal lavage has not yet been made. The reproductive status of the male, who would now be somewhat more than a year old, is not known, although erections have been noticed.

Observations on other aspects of the special physiology and behaviour of the tarsiers are being continued.

Formation of Cleistogamic and Chasmogamic Flowers in Wild Violets as a Photoperiodic Response

IN the spring of 1938, an investigation was undertaken to study experimentally the physiological conditions for cleistogamy in violets. It seemed obvious that the results of Bergdolt[1] do not offer a satisfactory explanation of the occurrence of this phenomenon in Nature. Nutritional difficulties are not likely to occur suddenly and so regularly as to account for the seasonal appearance of cleistogamic and chasmogamic flowers. As a matter of fact, most of his experiments also indicate an influence of the photoperiod. Curiously enough, Uphof[2] in his review of cleistogamic flowers overlooked the influence of this ecological factor, although a detailed investigation by Allard[3] showed the decisive effect of the photoperiod for the formation of cleistogamic and chasmogamic flowers in the hog peanut (*Falcata comosa*). Garner and Allard[4] also report on the influence of day-length actually for a species of violet (*Viola fimbriatula*).

Consequently I considered it appropriate to make a detailed study on the influence of the photoperiodical response on wild violets. My assumption has proved correct with regard to flower-formation. I have investigated the effect with the following species: *Viola biflora, canina, hirta, odorata, mirabilis, palustris, riviniana, silvestris*. Different species need different lengths of day. As a general rule, however, photoperiods less than twelve hours produce no flowers; with photoperiods between 13 and 15 hours, chasmogamic flowers normally appear; and when the photoperiod exceeds 17 hours, cleistogamic flowers appear. Additional morphological reactions have been observed. The plants have been grown in pots under identical conditions and the various flower types appear regardless of the season. Cleistogamic flower-buds fall off when transferred to a shorter photoperiod. Chasmogamic buds differ in the reaction to prolonged day-lengths. The induction of rejuvenation and everblooming responses are being investigated, and the study will be extended to elucidate the modifying effect of other ecological factors.

These results give a probable explanation of the fact that violets commonly flower for the second time in the autumn, and that cleistogamic flowers occur regularly in the summer. Most likely this photoperiodic reaction accounts partly for the fact that the alpine violets mainly are chasmogamic (Schroeterer[5]), while cleistogamy is a conspicuous feature of the violets in the northern countries and especially in the Scandinavian mountains (Lindman[6]). Other factors, especially the existence of different ecotypes, must however also be taken into consideration.

A detailed account of these experiments will be published later.

Genetical Proof of the Existence of Coffee Endosperm

IN the last few years several opinions have been published regarding the nature of the nutritive tissue of the coffee seed. Houk[1] came to the conclusion that the bulk of the mature coffee seed is perisperm formed by an enlarged nucellus, the scantily formed endosperm being evanescent. In a second paper[2] the same author puts forward the view that nucellus and integument of the ovule are so intimately fused that they cannot be distinguished from each other. This hypothesis of the 'integument-nucellus' had already been proposed by Lloyd[3]. Mayne[4] does not agree with Houk's assumption, and states that endosperm formation passes through a long rest period shortly after fertilization; meanwhile the nucellar tissue develops, evolving the true endosperm; later on, however, the endosperm begins to grow rapidly, replacing the nucellar tissue, which in the mature seed is represented by the inner layer of the 'silver skin'. Leliveld[5] confirms von Faber's[6] opinion, that the coffee ovule contains a very small nucellus "surrounded by a single stout integument". As the seed develops, the nucellar tissue is supposed to be suppressed and the integument enlarges, surrounding the embryo-sac. Endosperm formation is induced later on; it then takes all the space in the seed, the remnants of the integument finally forming the silver skin. The author claims to have determined the triploid nature of the endosperm by actual chromosome counts. Joshi[7] also agrees with von Faber that the ovule of coffee "has a weakly developed nucellus and a massive integument"; but he seems to agree with Houk that the nutritive tissue of the coffee seed is of maternal origin.

In the present note, we wish to put forward a genetical proof for the existence of true endosperm in the mature coffee seed. A few years ago a new mutant of *Coffea arabica* L. called 'Cêra'[8], which differs from the normal *Coffea arabica* varieties by having *yellow* seeds, was found in two coffee-growing regions of the State of São Paulo. Cutting through a mature seed, one notes that the whole of its nutritive tissue is of that colour. Yellow seeds are easily distinguished from normal green coffee beans. A genetical analysis of this new character, as yet not complete, furnished the following preliminary results:

(*a*) plants grown from *yellow* 'Cêra' seeds produced seeds of the same colour when the flowers were selfed;

(*b*) pollinating flowers of these plants with pollen of normal *green* seeded individuals (*C. arabica* L.), *green* hybrid seeds were always produced; the colour of these hybrid seeds cannot be distinguished from that of pure green seeds;

(*c*) pollinating flowers of 'Cêra' plants with pollen of *C. excelsa* Chevalier and *C. liberica* Hiern., which also have *yellow* seeds, hybrid seeds of the same colour were always obtained.

The results of (*b*) prove that a typical case of xenia occurred, one gene (or genes) for green colour dominating entirely two genes (or more) for yellow colour derived from the polar nuclei of the embryo-sac.

As the production of green hybrid seeds in the crosses between 'Cêra' type and normal green-seeded varieties is not likely to be explained by the occurrence of metaxenia, it is concluded that the bulk of the mature coffee seed is formed by real endosperm.

Natural Variances of Mental Tests, and the Symmetry Criterion

When two correlation matrices R_1 and R_2 have a *symmetrical* product $R_1R_2 = R_2R_1$, they have the same latent vectors[1,2], and Prof. Cyril Burt has recently proposed[3] to use this as a criterion that two batteries of mental tests contain the same mental 'factors'. I do not myself think that one can draw any safe conclusions about identity of factors in two batteries unless some tests are common to both batteries. But if one accepts Burt's criterion, I wish to point out that when R_1R_2 is asymmetrical, the product of the *covariance* matrices $D_1R_1D_1$ and $D_2R_2D_2$ may conceivably be symmetrical, where D_1 and D_2 are diagonal matrices of standard deviations. If an experimenter therefore has psychological reasons for thinking that two batteries contain identical factors, but finds R_1R_2 to be asymmetric, he may be able to discover variances which would make the product $D_1R_1D_1D_2R_2D_2$ symmetric. In that case he would have considerable reason for assuming these to be the natural variances of these tests.

Effect of Tube-Length on the Visibility of Dust Particles with an Oil-immersion Objective

The phenomenon described by Messrs. Beadle and Patterson in Nature of August 19, p. 327, is well known to practical microscopists, since it occurs whenever a considerable change in the working aperture of a wide-angled objective is made, and admits of a simple explanation.

It is generally admitted that the perfect correction of all the zones of a high aperture oil-immersion objective for spherical aberration is a practical impossibility. It is therefore usual for the computer to concentrate on the inner and outer thirds of the aperture, leaving an intermediate zone in which the corrections are less accurate. When adjusting the tube-length for such an objective under full aperture conditions, the predominating rays for which symmetry of defocusing is obtained are those from the two preferred zones mentioned above.

In the case of the examination of objects mounted dry upon the cover, and of such a nature that no stray light is reflected or refracted into the portion in excess of N.A. 1·0, the first and intermediate zones only are in use, and since the corrections for the rays from the latter will but rarely coincide exactly with those for the outer zone, a change in tube-length will almost certainly be required. The extent of this alteration, and whether plus or minus, will depend entirely on the skill and inclination of the computer, and the figure given by Messrs. Beadle and Patterson of minus 20 mm. to 30 mm. cannot therefore be regarded as having any scientific significance.

Dipterous Larvæ and Wound Treatment

During the war of 1914–18, W. S. Baer[1], in the United States, noticed that when troops wounded in battle had been lying out on the ground unattended for some time, their wounds very commonly became infested with larvæ of certain kinds of flies. He noticed specially that when the wounds had acquired about their maximum maggot population they did not exhibit dangerous after-effects. On the other hand, men whose wounds had received prompt early treatment often developed infection. It was found that the presence of these larvæ was especially beneficial in cases of osteomyelitis. It was discovered that the larvæ were eating the necrotic tissue which was supporting the main bacterial infection, and at the same time these larvæ were inhibiting further bacterial growth. Stewart[2] claimed that the scavenging larvæ play an important part in clearing the necrotic tissue, but that calcium carbonate, which is constantly excreted by the larvæ, is also important in alkalizing the medium (the wound) in which the bacteria live, and of increasing phagocytic activity.

The larvæ used in the earlier treatment of osteomyelitis belonged chiefly to the species *Lucilia sericata* (Meig.), *L. cæsar* (L.) and *Phormia regina* (Meig.). Stewart[3] showed, however, that due precautions must be taken, and a proper knowledge of the biology of these larvæ is essential. Some species will feed on both necrotic and normal tissue and are potentially dangerous to the latter.

Much study has been devoted to the technique of rearing dipterous larvæ under aseptic conditions, and also of retarding their normal development until they were actually needed for implantation within wounds. Sterilization of the eggs in a 5 per cent solution of formaldehyde mixed with a 1 per cent solution of sodium hydroxide for five minutes has been found satisfactory by Robinson[4]. The full details of this process, and that of the subsequent rearing of the larvæ, is given by the last-named author. Livingston and Prince[5] were successful in eliminating the inconvenience and unpleasantness associated with the actual 'maggot therapathy' by using a sterile extract of the creatures themselves. Robinson[6] claimed that the blow-fly larvæ contain allantoin in their excretion, and that the rapid healing of wounds as the result of 'maggot therapathy', is due in the main to this agent. He did not claim, however, that it could be entirely substituted for the application of the living larvæ. Robinson carried his investigations further and found that a watery solution of allantoin provides the necessary healing agent, without the presence of dipterous larvæ at all. In 1935 allantoin was a rare chemical in the laboratory, but it soon came to be made synthetically. Robinson also pointed out that a part of the allantoin molecule can be split off by hydrolysis to form urea. Further work led to the discovery that a 2 per cent water solution of urea has the equal healing properties of allantoin or of the fly larvæ themselves. It has the further advantage of being much cheaper than allantoin.

Not only osteomyelitis, but also many other kinds of non-healing wounds, have been treated in the manner just described, including gangrene, heat burns, X-ray burns, varicose and diabetic ulcers, etc. So far as I am aware, Paramonow in 1934[7] was the first to use dipterous larvæ in the treatment of gas gangrene. He applied maggots of the house fly, *Musca domestica*, since Calliphora larvæ were prone to devour healthy as well as necrotic tissue. He states that he cured three cases of gas gangrene when amputation appeared inevitable, and that the healing process set in 48 hours after the treatment began.

In this brief summary, I have stated the present position of the subject in so far as it is known to me. It is desirable, at the present early stage in the world calamity that we are facing, that the foregoing information should be made as widely known as possible. There is no doubt that further research into the technique of this method is urgently required. Also, I believe that it is correct to say that this method of wound treatment has been more widely explored in the United States than in England. The literature on the subject is already extensive, and I have only mentioned a few of the chief writings here.

Points from Foregoing Letters

In view of the large apparent difference between the sensitivities of bean roots to neutrons and γ-rays, a search was made by L. H. Gray and J. Read for possible contributions to the energy absorption in tissue resulting from neutron irradiation, such as induced radioactivity. The activity induced in ashed grass was measured experimentally, and was found to correspond to a quite inappreciable contribution to the total energy absorption. The difference in sensitivity to neutrons and γ-rays is therefore considered to be real.

The scattering cross-sections of various elements for D—D neutrons have been measured by W. D. Allen and C. Hurst, using phosphorus as a fast neutron detector The cross-sections thus observed are smaller than those obtained by previous experimenters.

The superficial oxide films formed on aluminium containing small admixtures of beryllium or magnesium are found by S. Dobiński and M. Nieśluchowski to consist in most cases of BeO or MgO, even when the additional element is present at so low a concentration as 0·03 per cent in the case of magnesium.

When testing a new Coolidge tube with molybdenum target, I. Koga and M. Tatibana observed brilliant spots and scratch markings on the target while X-rays were being emitted. They suggest that the spots are due to electronic bombardment of minute protrusions from the surface of the target. Jan Forman describes similar appearances which were noted when using multi-segment magnetrons under certain conditions; the luminescent points were on the backs of the anode segments. He has also seen a similar effect in a Farnsworth cold cathode multiplier.

According to results obtained by P. György and R. E. Eckardt, the part played by the vitamin B$_2$ complex in dermatologic conditions has to be extended beyond vitamin B$_6$. In the presence of vitamins B$_1$ and B$_6$ and riboflavin, three further types of dermatologic conditions were observed.

M. Landy has confirmed earlier work by other investigators, who showed that some strains of hæmolytic streptococci can be grown on a peptone base medium supplemented with glutamine; but when the peptone is replaced by a stock amino-acid mixture frequently used for nutritional studies, he finds no growth, suggesting that peptone contains a necessary growth factor.

A. K. Balls and H. Lineweaver state that the exposure of crystalline papain to iodoacetate, or for longer periods to cystine, resulted in the disappearance of sulphhydryl as determined by a titration with iodine on the later denatured protein. The loss corresponded approximately to one –SH group per molecule of the enzyme protein inactivated by the reagent. Qualitative tests for –SH with nitroprusside in the absence of added cyanide were positive only on denatured protein that had not been treated with iodoacetate or cystine. The results permit the conclusion that an –SH group or the precursor thereof is essential to the enzymic activity of papain. It is also evident that native proteins exist for which the nitroprusside test is not informative.

H. A. Krebs and P. P. Cohen describe a 'dismutation' between α-ketoglutaric and α-iminoglutaric acids leading to the formation of glutamic acid, succinic acid and carbon dioxide. The reaction is an intermediary process in the metabolism of heart and kidney.

H. R. Catchpole and J. F. Fulton give an account of the first recorded survival of the spectral tarsiers in captivity outside the area of their normal distribution (Melanesia). A pair were brought from Surigao in the Philippines to New Haven, Conn., U.S.A., in November 1938, and they are now thriving under laboratory conditions. The female is mature and has exhibited regular œstral cycles of 23–28 days duration.

The photoperiodical response of several Swedish violas has been studied experimentally by G. Borgstrom. It seems that chasmogamy and cleistogamy are due to different photoperiods. When the photoperiod is less than 15 hours chasmogamic flowers normally appear, and when exceeding this day length cleistogamic flowers occur. Several additional morphological responses have been observed. These results partly account for the occurrence of these different flower-types in Nature.

G. H. Thomson points out that Burt's symmetry criterion for identity of mental factors in two batteries of tests, if accepted, may conceivably enable the natural variances of such tests to be ascertained.

A mutant coffee growing in Brazil has seeds which are yellow throughout. Pollination of these plants with normal green-seeded coffee produces hybrid seeds which are green, according to C. A. Krug and A. Carvalho. It is inferred that true endosperm constitutes the bulk of the mature coffee seed.

RESEARCH ITEMS

Two Bronze Age Cairns in Wales

THE report on the excavation by Sir Cyril Fox of the Simondston and Pond Cairns, Coity Higher Parish, Bridgend, Vale of Glamorgan, which appeared originally in *Archæologia* (87, 129–180, 1938), has now been issued in reprint as a publication of the National Museum of Wales (Cardiff: 1939, pp. 51, 2*s*. 6*d*.). Of the two cairns, that at Simondston is the earlier, its primary deposits in 'enlarged food vessels' indicating a date in Middle Bronze Age A, about 1500 B.C.; while the Pond cairn is definitely later, the deep collar of its well-wrought cremation urn belonging to Middle Bronze Age B, say 150 years later, or about 1300 B.C. Both cairns being situated on Lias limestone, the economic basis of their makers was similar, depending on a forest growth, mainly ash and other trees demanding calcareous soil, such as was widely occupied in neolithic and bronze age times in the Vale. The differences between the culture of the Simondston cairn and that of the Pond cairn are so profound that the latter must be regarded as intrusive in the district, while the former represents an ancient cultural tradition, the megalithic. The Pond cairn culture seems to be that of settlers from the other side of the Severn sea. Co-operation with workers in other fields of science (of which the results are here printed in appendixes) have produced results which indicate that the suggestion that the time had come to intermit for a period field-research on 'round barrows' was premature. Thus the present investigation has produced the first scientifically controlled record of wheat in the bronze age of Britain, the earliest record of barley, the identification of the charcoals of the fuels used for pyres and other purposes, and evidences of the use of coal in the bronze age in South Wales.

Standards of Physical Development in School Boys

IN view of the lack of standards based on recorded measurement of groups of adolescents, whose home environment, health record, and heritage present favourable conditions, an investigation was undertaken by H. Bathurst Norman of 500 public school boys, who in every case exceeded the standard required of the nutritive elements for the maintenance of perfect health, and for purposes of comparison, a homogeneous group of 501 secondary school boys, such as those among whom, according to current reports, the diet compares unfavourably with that of public school boys. The age groups range from thirteen to nineteen years; and the height, weight, sitting height, lumbar pull, and chest girth in expiration and inspiration were recorded (*Lancet*, August 19). There are significant differences in the results of the two groups. At each year between the ages of fourteen and eighteen a boy of Group I is approximately 16 lb. heavier and 3 in. taller than a boy of Group II. His lumbar pull is 30 lb. greater. The difference in height is shown, by measurement of sitting height, to be due to difference in the length of leg; while a record of ratio of weight to height shows a greater weight per unit of height in the public school group. The differences in physique are maintained roughly throughout the age periods under review. There is no progressive deterioration in the secondary school boy, nor any obvious tendency in the higher ages to approximate to the older of the public school boys. There is no abnormal acceleration of growth in either group. Heredity is an important influence in determining stature, but the real correlation is one of diet rather than of inherited genes. The limits of growth are due to heredity; but how nearly the limits are approached depends upon a variety of environmental conditions, of which correct nutrition during the growing period is one of the most important.

Penaeids of the John Murray Expedition

DR. RAMADAN has recently described an interesting series of Penaeids (excluding the genera Benthesicymus and Gennadas of the sub-family Aristaeinæ) (Crustacea: Penaeidæ. British Museum (Natural History), The John Murray Expedition 1933–34. Scientific Reports, 5, No. 3; 1938). The material is rich, and besides this a number of Penaeidæ in the collection of the British Museum material obtained by the German Deep Sea Expedition and other specimens have been examined for comparison. The descriptions are critical and detailed. A key is given to the genera of the Aristeæ, the chief distinction being the presence or absence of a hepatic spine on the carapace and the presence or absence (or reduction) of podobranch on the third leg and epipodite on the fourth. Seven (or perhaps eight) species of Aristeus are known, four of which, including two new species, are represented here. In discussing the genus Plesiopenaeus (p. 50) the author contradicts himself, for in paragraph 1 it is stated that *P. edwardsianus* does not possess exopodites on the walking legs, whilst in paragraph 3 they are stated to occur in this species. Again, on p. 51 it is inferred that they are absent. As Bouvier distinctly says that exopodites on the walking legs are absent in *P. edwardsianus*, the first statement is almost certainly correct and the second a slip; but an important slip in this case when the validity of the genus Aristeopsis is involved. Dr. Ramadan agrees with Burkenroad that Aristeopsis should be regarded as a synonym of Plesiopenaeus.

White Rot of the Elm

THE fungus *Ustulina vulgaris* causes the rotting of several kinds of forest trees, and its depredations have formed the subject of a recent series of papers by Mr. W. H. Wilkins. He has lately considered the parasitism of the organism upon elm (*Trans. Brit. Mycol. Soc.*, 23, Pt. 2; July 1939), and proved its pathogenicity by isolation of the fungus and re-infection. The sap-wood of the host is not attacked: but cells of the heart-wood apparently lose their starch and become discoloured, though no fungal hyphæ have been found. Patches of diseased wood occur, however, delimited by a black line, and hyphæ occur within this zone. It is suggested that parasitism of the fungus occurs in two stages, namely, infiltration, where products of the organism diffuse into healthy heart-wood, and cellular disintegration, which progresses only in the presence of the fungus. The disease is similar to a white rot of the lime, caused by the same pathogen.

Rayleigh Waves in an Inner Stratum of the Earth

K. Sezawa and K. Kanai, by mathematical calculation (*Bull. Earthq. Res. Inst., Tokyo*, 17, Pt. 2, 179–189; 1939) have determined several properties of Rayleigh waves such as can exist and be transmitted through an inner stratum of the earth. Some of the more important of these properties may be summarized as follows. In every case the velocity of the boundary waves ranges between the velocity of distortional waves in the stratum and that in the adjacent media. In the case of the displacement distribution of the waves that is symmetrical with respect to the middle plane of the stratum, there is only one dispersion curve for any ratio of μ' to μ. In the case of the distribution that is anti-symmetrical with respect to the middle plane, there are in general a number of dispersion curves for certain ratios of μ'/μ. These dispersion curves correspond to the waves of the fundamental and higher order types, namely, waves with several nodal planes of vibration parallel to the stratum. Yet even in the case of waves of anti-symmetrical vibration, if the velocity of distortional waves in the stratum is higher than that in the outer media, there is only one dispersion curve that corresponds to waves of fundamental vibration. The ordinates of the dispersion curves at abscissa $L/H = 0$ represent the velocities of Stoneley waves that are transmitted along any one boundary between the inner layer and the outer media.

Magnetic Observations in Sweden

WE have just received the second part of the report of the general earth magnetic investigation which was carried out during the period 1928–34 by the Geological Survey of Sweden. The first part of the report was published in 1936 under the title "A General Earth Magnetic Investigation of Sweden. Part 1—Declination S.G.U. Ser. Ca. No. 25", and this second part, which is No. 29 of the same series, entitled "Inclination", was compiled by Dr. Kurt Molin. Older determinations have been taken into account, as have also the measurements made by the Hydrographic Service of Sweden, but the chief part of the work has been done by seven persons on twenty expeditions. There were 2,257 observation places with an average of one I point in 177 km.^{2} and a rather greater density in Skåne. Dip circles were used throughout. For the mountainous districts, on account of its lightness, Chasselon dip circle No. 84 having a needle 6·5 cm. long was used, but owing to this not being so accurate as the other dip circles such as the Dover 8·9 cm., Casella 8·7 cm. and Gambey 25 cm., it was not used after 1931. An account of the corrections made and the method of reduction of the observations to the main epoch 1933·5 is given, together with explanatory maps and graphs. The main inclination table covers 42 pages, giving in each case the name of the station, latitude, longitude from Stockholm, altitude, geology, date of observation, values of dip in 1928·5, number of observations, average error, inclination in 1929·5 and 1933·5, and 1933·5 observed-calculated values. Four very valuable and beautiful colour-printed maps appended give: (1) inclination for epoch, July 1, 1933, (2) lines of equal anomaly, (3) values of anomaly of inclination, and (4) anomaly of inclination of Skåne. Since Sweden is interested economically in her iron ore deposits, this publication should be particularly valuable to Swedish authorities although it also affords a very valuable addition to the data of terrestrial magnetism and geology. Investigators interested in greater detail than it has been possible to give in this Swedish publication may obtain transcripts or photographic reproductions of the complete tables from the Geological Survey of Sweden.

Hydrolysis of Alkyl Halides

CONSIDERABLE controversy has centred around the interpretation of the rates of hydrolysis of alkyl halides by neutral water, one hypothesis assuming a slow dissociation of alkyl halide into halide ion and organic cation with an incomplete valency shell (an 'open sextet'), followed by the rapid reaction of this cation with water to yield alcohol and hydrogen ion, whilst the other hypothesis postulates that the rate-determining step is a bimolecular reaction of a water molecule with alkyl halide to yield halide ion and a cation the valency shell of which is completed by co-ordination of a previously unshared electron pair of a water molecule. R. A. Ogg, jun. (*J. Amer. Chem. Soc.*, 61, 1946; 1939), has reviewed the energetics of the various reactions and finds that the dissociation of an alkyl halide (in aqueous solution) into a methyl ion with an 'open sextet' and a halide ion is endothermic by at least 50 k. cal. per mol, and more probably by 70 k. cal. On the other hand, reaction with water to yield halide ion and the co-ordinated methyl ion CH_3OH_2+ is practically thermoneutral. Comparison with the experimental data for methyl halide hydrolysis shows that the first hypothesis stated (involving CH_3+) is much less probable than the second (involving CH_3OH_2+). It is suggested that carbonium ions with an open sextet never play an appreciable part in observable organic reactions and that mechanisms involving such ions should be abandoned.

Vitamins K_1 and K_2

THE antihæmorrhagic vitamins have recently been isolated in a condition of demonstrated purity and some work on the degradation of vitamin K_1 has been reported, so that preliminary suggestions as to their structure have been made. The evidence from the degradations is incomplete and in some points uncertain, so that L. F. Fieser, W. P. Campbell and E. M. Fry (*J. Amer. Chem. Soc.*, 61, 2206; 1939) have made some synthetic studies of quinones related to vitamins K_1 and K_2. The quinonoid character of the two vitamins was reported by Doisy, and it now appears that the absorption spectra of the vitamins resemble those of 1,4-naphthoquinones more closely than those of other series. Such a structure would account for a number of properties of the substances, and the chemical properties and absorption spectra of synthetic model compounds, as well as the marked antihæmorrhagic activity of 2,3-dimethyl-1,4-naphthoquinone (assayed by the Almquist procedure), lend support to the formulation of vitamin K_1 as 2-methyl-(or ethyl) 3-phytyl-1,4-naphthoquinone and of vitamin K_2 as 2,3-difarnesyl-1,4-naphthoquinone. The purple colour reaction of β-unsaturated alkyl naphthoquinones with sodium ethylate is shown to involve the replacement of the unsaturated side chain by hydroxyl, which accounts for the formation of a phthiocol-like pigment as the end-product of the colour reaction with vitamin K concentrates, and the pigment is probably phthiocol or the ethyl homologue. The phthiocol isolated from human tubercle bacilli may have arisen from the alkaline cleavage of a K-type vitamin.

SOCIOLOGICAL ASPECTS OF THE CINEMA

THE sociological and psychological importance of the film was under review in four papers at the first meeting of the Psychology Section of the British Association at Dundee on August 31. The discussion ranged from the film tastes of the adult to the uses that could be made of the film in the classroom, and in this connexion the question was raised whether sufficient attention is being given to the possible uses of the cinema apart from entertainment.

Knowledge of its manifold uses is so meagre that a suggestion was put forward for the creation of a Cinema Research Institute with an income of £50,000 a year. The objects of such an institute would be to co-ordinate to their mutual advantage the conflicting viewpoints of the various sections of the trade; to equate the demands of the public with the financial, technical and artistic resources of the industry, and lastly to use modern methods to discover the uses to which films could be put in the service of the modern democratic and world community. Its work would also be of value to Government Departments, official and semi-official bodies, municipal authorities, transport concerns, advertisers, social workers, and last but not least to the cinema industry itself.

The first investigation which it was suggested should be carried out was a general market research. There has never been any attempt to classify cinema-goers by age, sex or social categories. All that is known to-day is that the total number of regular cinema-goers in Great Britain in normal times is between 16 and 17 millions per week, with another 7 millions a week of more occasional visitors.

The second task a Cinema Research Institute should undertake is a research into the likes and dislikes of audiences by trained observers. The makers of films have certain 'hunches' that such and such a film will be a success, but the intuition is based on empirical calculations alone. Such an investigation would also doubtless show that the motives for attendance at the cinema are various. There are those who go to the 'pictures' for escape; the suburban housewife, for example, or the clerk or the manual worker slaving away at a monotonous job. There are, too, the courting couples who have no more interest in the pictures on the screen than in the man in the moon and to whom the comfort and isolation of the cinema is infinitely preferable to the chill of the city streets or the hardwood chairs and continuous interruptions of their own homes. Then there are those who go for an evening of good family entertainment on a regular day each week.

None of these groups is highly critical of the content of the films which they see. On the other hand, since receipts from films vary considerably, there must be a large but unknown number of people who pick and choose their film entertainment. Some go to see a particular star; others to see a dramatization of a play or a novel of which they have heard and which they think they will enjoy upon the film. Others go because their friends say that it is a good picture. Others because they have seen a good review in the 'fan' press or enjoyed the 'trailer' shown the week before. Lastly, there are the few who go to the films because they are interested in films as an art form similar to the theatre or music.

The last line of research that ought to be immediately undertaken is one into the film sociological and psychological effects. What, for example, will be the effect in international relations and political thought of the new tendency of the American film-makers to inject political propaganda into the films now being put upon the public screen? How far should the film be used for domestic government propaganda? The documentary or realist films sponsored by great interests like gas, oil or the General Post Office, are cases in point. "Housing Problems" directs attention to the need for better houses; "Enough to Eat" to problems of nutrition; "The Londoners" to the system and importance of local government; "Men in Danger" to industrial disease; or the American-made film "The River" to the Tennessee Valley Authority's work.

Nevertheless, in some respects all films have propagandist effect. The young people of to-day are better turned out than they used to be, and homes are more comfortable, all because of the effect of the film. Where one should draw the line between conscious and unconscious attempts to influence the filmgoer, is a question yet to be resolved. So far as the British public is concerned, direct propaganda rarely succeeds unless it is camouflaged as 'interest'.

The 'interest film' is capable of much further development. Both adults and children will stand for a great deal of education provided that it is not too obvious. Almost any pill will be swallowed if nicely coated with jam! Where so many amateur organizers of children's matinées go wrong, is that they bore their audiences and hence the experiment is unsuccessful. The professional children's matinée such as is run by some 700 picture houses in Great Britain is entertainment pure and simple. It consists of a good action film or serial, a cartoon sufficiently simple for children to understand, and an interest short film and a comedy. Dr. Inglis, of the University of Glasgow, made a plea for the film, which he said is not nearly so bad as it is painted, for it gives the children a love of adventure and a sense of beauty. It certainly has no effect on juvenile crime. In fact, closing these theatres would be likely to lead to an increase in anti-social conduct.

Side by side with the use of the film as children's entertainment runs the use of the film as one of the optical aids for children's instruction. Its value as a teaching aid has been abundantly proved. Films enable children to retain facts longer, open up the wider world around the child and, last but not least, instruct them in citizenship.

The reception given to this year's discussion emboldens one to suggest that the cinema is worthy of more than a sectional discussion and the committee might well consider if next year it should not form a topic for one of the evening lectures, perhaps under the auspices of the Division for the Social and International Relations of Science.

OLIVER BELL.

SOCIAL BIOLOGY AND POPULATION IMPROVEMENT

IN response to a request from Science Service, of Washington, D.C., for a reply to the question "How could the world's population be improved most effectively genetically ?", addressed to a number of scientific workers, the subjoined statement was prepared, and signed by those whose names appear at the end.

The question "How could the world's population be improved most effectively genetically ?" raises far broader problems than the purely biological ones, problems which the biologist unavoidably encounters as soon as he tries to get the principles of his own special field put into practice. For the effective genetic improvement of mankind is dependent upon major changes in social conditions, and correlative changes in human attitudes. In the first place, there can be no valid basis for estimating and comparing the intrinsic worth of different individuals, without economic and social conditions which provide approximately equal opportunities for all members of society instead of stratifying them from birth into classes with widely different privileges.

The second major hindrance to genetic improvement lies in the economic and political conditions which foster antagonism between different peoples, nations and 'races'. The removal of race prejudices and of the unscientific doctrine that good or bad genes are the monopoly of particular peoples or of persons with features of a given kind will not be possible, however, before the conditions which make for war and economic exploitation have been eliminated. This requires some effective sort of federation of the whole world, based on the common interests of all its peoples.

Thirdly, it cannot be expected that the raising of children will be influenced actively by considerations of the worth of future generations unless parents in general have a very considerable economic security and unless they are extended such adequate economic, medical, educational and other aids in the bearing and rearing of each additional child that the having of more children does not overburden either of them. As the woman is more especially affected by child-bearing and rearing, she must be given special protection to ensure that her reproductive duties do not interfere too greatly with her opportunities to participate in the life and work of the community at large. These objects cannot be achieved unless there is an organization of production primarily for the benefit of consumer and worker, unless the conditions of employment are adapted to the needs of parents and especially of mothers, and unless dwellings, towns and community services generally are reshaped with the good of children as one of their main objectives.

A fourth prerequisite for effective genetic improvement is the legalization, the universal dissemination, and the further development through scientific investigation, of ever more efficacious means of birth control, both negative and positive, that can be put into effect at all stages of the reproductive process—as by voluntary temporary or permanent sterilization, contraception, abortion (as a third line of defence), control of fertility and of the sexual cycle, artificial insemination, etc. Along with all this the development of social consciousness and responsibility in regard to the production of children is required, and this cannot be expected to be operative unless the above-mentioned economic and social conditions for its fulfilment are present, and unless the superstitious attitude towards sex and reproduction now prevalent has been replaced by a scientific and social attitude. This will result in its being regarded as an honour and a privilege, if not a duty, for a mother, married or unmarried, or for a couple, to have the best children possible, both in respect of their upbringing and of their genetic endowment, even where the latter would mean an artificial—though always voluntary—control over the process of parenthood.

Before people in general, or the State which is supposed to represent them, can be relied upon to adopt rational policies for the guidance of their reproduction, there will have to be, fifthly, a far wider spread of knowledge of biological principles and of recognition of the truth that both environment and heredity constitute dominating and inescapable complementary factors in human wellbeing, but factors both of which are under the potential control of man and admit of unlimited but interdependent progress. Betterment of environmental conditions enhances the opportunities for genetic betterment in the ways above indicated. But it must also be understood that the effect of the bettered environment is not a direct one on the germ cells and that the Lamarckian doctrine is fallacious, according to which the children of parents who have had better opportunities for physical and mental development inherit these improvements biologically, and according to which, in consequence, the dominant classes and peoples would have become genetically superior to the underprivileged ones. The intrinsic (genetic) characteristics of any generation can be better than those of the preceding generation only as a result of some kind of *selection*, that is, by those persons of the preceding generation who had a better genetic equipment having produced more offspring, on the whole, than the rest, either through conscious choice, or as an automatic result of the way in which they lived. Under modern civilized conditions such selection is far less likely to be automatic than under primitive conditions, hence some kind of conscious guidance of selection is called for. To make this possible, however, the population must first appreciate the force of the above principles, and the social value which a wisely guided selection would have.

Sixthly, conscious selection requires, in addition, an agreed direction or directions for selection to take, and these directions cannot be social ones, that is, for the good of mankind at large, unless social motives predominate in society. This in turn implies its socialized organization. The most important genetic objectives, from a social point of view, are the improvement of those genetic characteristics which make (*a*) for health, (*b*) for the complex called intelligence, and (*c*) for those temperamental qualities which favour fellow-feeling and social behaviour rather than those (to-day most esteemed by many) which make for personal 'success', as success is usually understood at present.

A more widespread understanding of biological principles will bring with it the realization that much more than the prevention of genetic deterioration is to be sought for, and that the raising of the level of the average of the population nearly to that of the highest now existing in isolated individuals, in regard to physical wellbeing, intelligence and temperamental qualities, is an achievement that would—so far as purely genetic considerations are concerned—be physically possible within a comparatively small number of generations. Thus everyone might look upon 'genius', combined of course with stability, as his birthright. As the course of evolution shows, this would represent no final stage at all, but only an earnest of still further progress in the future.

The effectiveness of such progress, however, would demand increasingly extensive and intensive research in human genetics and in the numerous fields of investigation correlated therewith. This would involve the co-operation of specialists in various branches of medicine, psychology, chemistry and, not least, the social sciences, with the improvement of the inner constitution of man himself as their central theme. The organization of the human body is marvellously intricate, and the study of its genetics is beset with special difficulties which require the prosecution of research in this field to be on a much vaster scale, as well as more exact and analytical, than hitherto contemplated. This can, however, come about when men's minds are turned from war and hate and the struggle for the elementary means of subsistence to larger aims, pursued in common.

The day when economic reconstruction will reach the stage where such human forces will be released is not yet, but it is the task of this generation to prepare for it, and all steps along the way will represent a gain, not only for the possibilities of the ultimate genetic improvement of man, to a degree seldom dreamed of hitherto, but at the same time, more directly, for human mastery over those more immediate evils which are so threatening our modern civilization.

CONTACTS OF RELIGION AND SCIENCE

SIR RICHARD GREGORY, in choosing "Contacts of Religion and Science" as the subject of his chairman's address prepared for the Division for the Social and International Relations of Science for the Dundee meeting of the British Association, selected from the many topics of discussion open to him the one which, perhaps, most consistently holds the interest of those who are laymen in the double application of the term. He could have rendered no better service in both provinces of thought than he did by clarifying the issues, which in the popular mind are so frequently, but as Sir Richard maintained, erroneously held to conflict.

At the very opening of his address Sir Richard made his point of view clear when, after defining religion as "the reaction to an inner impulse as to what is conceived to be sacred and arouses awe or reverence", and science as "the accumulation of knowledge of the properties of natural objects—animate and inanimate—in relation to man's needs and his understanding of them through the use of his intelligence", he went on to show that there can be no conflict between them when they are conceived as joining in a higher unity, in which "all who are searching earnestly for truth, are considered to be worshipping at the same shrine". The dogmatisms of a few generations ago, both of men of science and theologians, are now giving way to a more liberal spirit. As he said, "The study of science creates a feeling of infinite greatness in all who pursue it, and though it may lead to imperfect interpretation, its motive cannot be irreligious. . . . It is in the service of high ideals that science, without which we cannot live, and religion, without which most people see no meaning in life, can find a common field of action."

When Sir Richard had thus made clear his conception as a man of science of the relation between religion and science, he proceeded in a brief historical survey to show what had been in fact the interactions of religion and science. Making special reference to the science of astronomy, he traced these relations from their beginnings in primitive forms of society, through their development in the civilizations of Mesopotamia, Egypt, India, the cosmogonies of the Greeks, the beginnings of modern scientific astronomical and physical knowledge down to Darwinism and the development of the theory of evolution, "which placed man in a new relationship to the rest of living creatures".

In regard to evolutionary theory, or rather its mechanism, the struggle for existence, Sir Richard was at pains to point out the erroneous character of the view sometimes put forward that this is a striving after personal or national mastery at all costs—"a crude misconception repudiated alike by its founder, and by Huxley, its most powerful exponent, as contrary to the best ends of civilization". Further, man as "Nature's insurgent son", continually fighting against forces of evil which would destroy him, is yet able to survive by the use of his intelligence. "He may not know the reason for his existence, but he does know that there is a law and order in the natural world, and if he breaks them, the penalty is inevitable. He has to obey the laws of Nature in order to survive."

Lest the charge of materialism should be brought against him for such doctrine, Sir Richard went on to show in effect that no break in the logical chain of argument, such as is sometimes imputed, is required to find a place for faith in such a view of Nature. For while "science is unable to provide any positive evidence for survival of personality after death—that belief is a powerful ethical factor in human development. It is just as permissible, therefore, to assume that another world awaits habitation by an exalted type of humanity after this earth has come to an end, as it is to believe in the eternal existence of personality."

In conclusion, Sir Richard once more emphasized the historical note. The attempts to find support for Christian belief in general, and the Mosaic account of Creation in particular, in naturalistic or rationalistic explanations, or those which aimed at fitting new knowledge into a system of thought having no claims to scientific accuracy, served no useful purpose to the Bible or to science. A much sounder basis was to be found in applying evolutionary principles to religious thought and studying sacred books as stages in man's progressive discovery in theology. In science there are no final interpretations or unchangeable hypotheses; and when the same principle is recognized in theology, religion will share some of the vitality of the natural sciences. "It is through the acceptance of the idea of evolution in the spirit, as well as in the body of man, that the partition which formerly separated religion and science is being dissolved."

THE ANCESTORS OF THE EUTHERIA

By Dr. A. A. Abbie, Department of Anatomy, University of Sydney

WHATEVER may be the opinions of individual investigators, or even of groups of investigators, as to the status of the ancestors of the eutherian mammals, there has not as yet appeared any conclusive evidence which can determine the issue in favour of any one of the several theories available. Dentition, placentation, details of the skeleton and other somatic characters have all alike failed to supply a decisive solution to the problem. The ancestors may have been amphibians, reptiles, monotremes or marsupials; the Eutheria may have been derived together with the Prototheria and the Metatheria from a common ancestor; or the placentals may own one ancestor, the monotremes and marsupials another; or they may all have arisen independently from distinct pre-mammalian ancestors. At the present moment any of these propositions could be advanced with little fear of contradiction, although a general consensus of opinion would probably be found to favour descent of the Eutheria from some primitive, marsupial-like predecessor.

While bearing in mind Graham Kerr's caution against building too much upon the evidence of a single system, it may be asserted, nevertheless, that in the brain there appears a structure—the corpus callosum—which is peculiar to the Placentalia[1,2,3], and that if the conditions essential to the formation of a corpus callosum could be defined with sufficient precision, they would provide a guide to the structure of the brain in the ancestor of the Eutheria.

Elliot Smith presented the view that the corpus callosum is produced by infiltration of the dorsal part

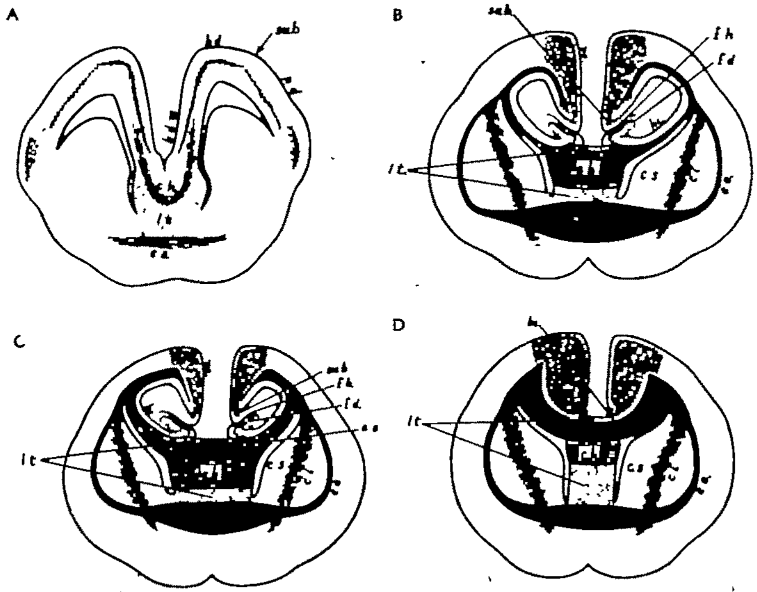

Fig. 1.

B, C, D, STAGES IN THE EVOLUTION OF THE CORPUS CALLOSUM ACCORDING TO ELLIOT SMITH: THE NEOCORTICAL FIBRES ARE SAID TO PASS THROUGH THE HIPPOCAMPAL COMMISSURE VENTRAL TO THE HIPPOCAMPUS.

(For key to lettering, see end of article).

of the hippocampal commissure with neocortical fibres which pass ventral to the hippocampus (Fig. 1, *B*, *C*). The hippocampus above the callosum then atrophies to the attenuated remnant which is represented chiefly by the indusium griseum (*C*). Elliot Smith expressed the opinion that the new neocortical connexion had been imposed upon the hippocampal commissure of marsupials, but a glance at *A* will indicate that it might as readily have been imposed upon that of reptiles—or even of amphibians, for that matter. His work, then, left the problem no closer to solution than before.

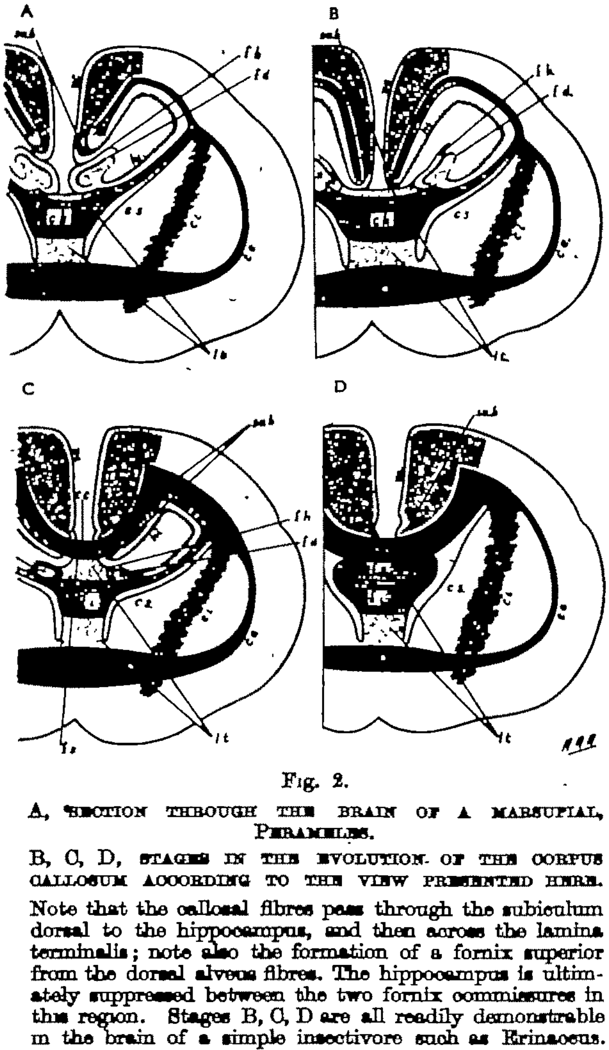

Fig. 2.

A, SECTION THROUGH THE BRAIN OF A MARSUPIAL, PERAMELES.

B, C, D, STAGES IN THE EVOLUTION OF THE CORPUS CALLOSUM ACCORDING TO THE VIEW PRESENTED HERE.

Note that the callosal fibres pass through the subiculum dorsal to the hippocampus, and then across the lamina terminalis; note also the formation of a fornix superior from the dorsal alveus fibres. The hippocampus is ultimately suppressed between the two fornix commissures in this region. Stages B, C, D are all readily demonstrable in the brain of a simple insectivore such as Erinaceus. All figures semi-schematic. (For key to lettering, see end of article.)

It has been shown[3] that in reality the corpus callosum has appeared in quite a different manner. The neocortical fibres do not pass ventral to the hippocampus and through the hippocampal commissure; on the contrary, they pass through the subiculum dorsal to the hippocampus, separating this from the neocortex (Fig. 2, *A*, *B*, *C*). Thus the supra-callosal structure is really a lip of subiculum everted by the pressure of the issuing callosal fibres (*D*). Incidentally, these neocortical fibres carry on their ventral aspect some of the dorsal alveus fibres from the hippocampus to form a second hippocampal commissure—the fornix superior.

The callosal fibres, then, pass directly through the medial wall of the hemisphere at the subiculum, and cross on the dorsal aspect of the lamina terminalis to reach the opposite hemisphere. In the submammalia the subiculum is far removed from the lamina terminalis, its representative being found probably on the dorso-lateral aspect of the hemisphere (Fig. 1, *A*). It is clear that an essential preliminary to the production of a corpus callosum in the manner just described is approximation of the subiculum to the lamina terminalis. Such approximation is achieved when expansion of the neopallium produces the characteristic inrolling of the hippocampus with the formation of a hippocampal fissure; at this stage of evolution the subiculum lies at the apex of the dorsal lip of the hippocampal fissure[4] in close anatomical relationship with the lamina terminalis (Fig. 2, *A*).

Expansion of the neocortex and the consequent formation of a hippocampal fissure are the minimum essentials to the production of a corpus callosum, and this condition is first realized in the brain of monotremes and marsupials. The ancestor of the Eutheria must, therefore, be sought in these two groups of mammals, not among the pre-mammalia.

The ancestors of the monotremes are little known, while the brain in existing representatives of this group is far too specialized to serve as a starting point for the Eutheria. Among marsupials, the possession of a fasciculus aberrans in the anterior commissure[5,6] immediately excludes all Diprotodontia. Of the Polyprotodontia, such representatives as the Cænolestidæ and Peramelidæ, Myrmecobius, Notoryctes, Sarcophilus, Thylacinus and some of the Didelphiidæ are all too specialized in other directions to serve as possible candidates, and there remain only some of the Didelphiidæ and Dasyurinæ, and the Phascogalinæ. Finally, assuming that the possession of a pouch constitutes another bar to direct ancestry, the ultimate choice must fall upon some small pouch-less phascogale or didelphid of bodily structure sufficiently generalized to approximate that of the insectivore-like primitive placentals.

A word of personal explanation is probably required. The late Sir Grafton Elliot Smith was my teacher and friend, and what I know of science I learnt from him; but he was a man in whom scientific accuracy outweighed all personal considerations, and this paper is published in the knowledge that were he still alive, such would have been his wish.

c.a., anterior commissure

A MESOLITHIC SETTLEMENT IN SURREY

THE discovery of a mesolithic village at Farnham, Surrey, was due in the first instance to Mr. W. F. Rankine, who established the fact of mesolithic occupation on the Farnham Valley Sewage Farm in 1929 in the course of a surface survey of the district. Trial excavations were carried out during 1930–35. Mr. J. G. D. Clark, recognizing the importance of the site, then undertook its systematic investigation. Excavations were carried out by him in 1937–38, Mr. Rankine co-operating. A report on the results of the excavations has been prepared under their joint authorship and is now available[1].

The village is situated to the north-east of Farnham on the gravel of the old course of the Blackwater at a height of 250 ft. above O.D. Water supply and geographical conditions combined to make the site attractive to early man, as is indicated by the discovery of archæological remains of many periods, ranging from Neolithic to Romano-British.

The trial excavations revealed the existence of some eighteen depressions in the gravel, some rich in worked and burnt flints, and most of them between three and four feet deep. The area selected for intensive work was a small rectangle showing less evidence of surface disturbance than other parts of the site. Here in 1937 three pits were discovered. These had a reddish-brown soil infilling, rich in worked and burnt flints. From Pit I, nowhere more than three feet in depth below the modern surface, some 851 crackled and more than 3,464 worked flints were recovered, while in a fourth pit, located and cleared in 1938, in which the floor had been cut through the gravel into red clay, 10,709 worked flints and 3,880 burnt flints were found. This pit was shown to be situated in a sandy hollow in the nature of a swallow hole, into which flints had been swept in mesolithic times. Flints were recovered to the number of 12,135 worked and 6,847 calcined. No significant differences in type were shown by flints from different levels. Evidences of Neolithic B occupation were found, but it is clear that the swallow hole had been choked with sand before neolithic peoples settled on the mesolithic site.

The size and contents of the pits and their general characteristics do not allow any doubt that they were dug as the floors of dwellings by the people whose worked flints were found in them. They were evidently intended for occupation over a considerable period of time; and in this connexion the existence of a permanent water-supply near by must be remembered. The excavation of these floors by their makers provided a certain amount of soil to serve for walls, on which roofs could be placed; but the irregular plan of the pits and the absence of post-holes argue against any kind of rigid frame construction. In regard to character and purpose, or mode of occupation, comparison may be instituted with the dwellings of Upper Palæolithic age investigated in Russia and Siberia and the earth-houses of recent circumpolar peoples.

Typological analysis of the flint implements found indicates a homogeneous industry, consisting of various types of microliths, of which slightly more than 30 per cent are geometric, flakes, scrapers, awls, burins, and core tools. Two techniques are to be noted, one core and the other flake. In the latter, microliths account for two-thirds of the whole.

Farnham is one of a number of sites in the area, extending to Aldershot, Guildford, Haslemere, and Bentley, on which the culture is essentially the same. Study of its distribution indicates the importance of geologico-ecological factors, and emphasizes the importance of water, and a subsoil of gravel or sand. Extending the survey to the south and east in Surrey, Sussex and parts of Kent, it would appear that the mesolithic sites are predominantly situated on the U-shaped band of Lower Greensand which surrounds the Weald, taking in sites at Dorking, Reigate, Redhill, and so far as East Malling, near Maidstone. A mace from Blackdown, now in the Haslemere Museum (and similar finds elsewhere), resembles a form from the heart of the Maglemose culture, which goes back to Boreal times. It is, therefore, evident that Farnham, Silmeston, Horsham, and other closely related sites form a group of industries differing in detail, but having in common features not found in combination elsewhere. They occupy a well-defined geographical area on analogous geological formations; and they therefore belong to a narrowly distributed but self-standing culture, for which the term Horsham culture has been proposed.

The key to the wider affinities of the Horsham culture is afforded in its combination of microlithic and core-axe elements—a combination which can be matched only in the Maglemose culture. While, however, the Maglemose strain must be recognized, certain differences must be admitted. The proportion of core axes is lower in relation to the microliths; and the microlithic forms are more varied. The microliths resemble most closely the Middle Tardenoisian of north-east France and Belgium. The Horsham culture, then, must be regarded as being basically Maglemosian, with a strong influence from Middle Tardenoisian. It is known that Maglemose spread over land now submerged, leaving outliers above modern sea-level in Holderness, East Anglia, the valley of the Thames and its tributaries, and probably the Isle of Wight and its hinterland. It was no doubt on the fringe of this territory on the western verge of the Maglemose culture-spread that the Middle Tardenoisian entered Britain; and it can scarcely be a coincidence that the Horsham culture, showing elements from both, is situated precisely in the zone of contact between the two.

Throughout history Britain has benefited from a variety of movements and influences from a variety of Continental sources. Already in mesolithic times two separate influences are to be seen flowing into England, one predominantly northern and the other predominantly western in character. The Horsham culture typifies the development of the British people which, drawing its inspiration from many sources, has yet managed to acquire its own distinctive features.

SCIENCE NEWS A CENTURY AGO

The Acoustics of Buildings

ON September 18, 1839, George Goodwin, jun., wrote to the editor of the *Civil Engineer and Architects' Journal*: "Sir. The report recently made to the Commissioners of Her Majesty's Treasury, by Messrs. Barry, De la Beche, W. Smith and Charles Henry Smith, on the sandstones, limestones and oolites of Great Britain . . . forms with the numerous tables and results of experiments by Messrs. Daniell and Wheatstone appended to it, one of the most valuable contributions to architectural science that has been made in modern times. . . .

"This being the case, then it must, I think, seem desirable to all that government should continue the good work . . . and I would venture to suggest touching the next step to be taken, the importance of appointing a committee to inquire into the most desirable forms of buildings, and the best mode of construction in a phonocamptic point of view, to investigate the science of sound and to deduce principles to be hereafter applied in the erection of buildings. On this subject, which is of the most vital importance to the excellence of the new houses of parliament, we are confessedly entirely ignorant (and I speak of not architects *alone*), we do not know so much as would enable one to say with certainty before a building be finished, whether or not it will be well adapted for oratorical purposes. . . . Sincerely therefore do I hope that a commission will be immediately appointed to collect information on the subject, and conduct a series of experiments on a large scale, without which nothing effectual can be looked for. . . ."

Chemical Powers of Light

"M. EDMOND BECQUEREL has recently communicated to the Académie des Sciences some important investigations on the chemical powers of solar light, which will probably lead to new and valuable results. It has been long known that light has the power of variously affecting certain chemical compounds; sometimes causing combination between two elements, and in other cases effecting the decomposition of compound substances; and it has been found that when a pencil of light is decomposed by passing through a prism of glass, those rays which possess this power are differently refracted from the coloured rays, and hence the existence of peculiar rays to which the name of Chemical Rays is given, has been deduced. The chief difficulty in experiments on these rays has been the slow nature of the action caused, and the difficulty of appreciating them. M. Becquerel has overcome these sources of uncertainty, and is enabled to study the chemical powers of light with ease, and measure the effects produced with considerable accuracy. The manner in which this is done is very simple. Two liquids of different densities, but both conductors of Electricity, and of such a nature as to act chemically upon each other when exposed to the influence of solar light are selected, and a portion of both is put into a cylindrical vessel blackened on the exterior". Plates of platinum are immersed in the liquids and connected to a delicate galvanometer. "If when thus arranged a ray of light is suffered to pass through the mass of the fluid, it causes chemical action to take place at the surface of contact of the two liquids, and a current of electricity which this sets in circulation is immediately rendered evident on the galvanometer. As the angle of deflection of the galvanometer indicates the power of the electric current, and as that is in exact proportion to the chemical action which originates it, it is evident that the arrangement gives an accurate measure of the chemical rays of light, at different times, from different sources, and under various circumstances" (*Athenæum*, September 21, 1839).

Tunnelling through the Alps

THE *Mechanics Magazine* of September 21, 1839, quoting from the *Mark Lane Express* said: "M. Vanino Volta, the engineer of Como, who in conjunction with M. Bruschetti of Milan, obtained in 1837, from the Austrian Government, a privilege of fifty years for the construction of a railroad between Milan and Como is now negotiating with the Swiss Cantons of Grisons and St. Gall, an enterprise which would vie in magnitude with the Thames Tunnel, viz., the piercing through the Grisons Alps. . . . M. Volta, reckoning that thirty years will be required to execute the works, demands an exclusive privilege of a hundred years with liberty to establish companies, in order to procure funds or to transfer his privileges to others."

SOCIOLOGICAL ASPECTS OF EVACUATION

THE complaints which are being received regarding the operation of evacuation schemes in England have at least the merit of preventing any undue complacency arising from the smoothness and efficiency with which the actual transport arrangements were carried out. The success of that operation and its fortunate freedom from attack might well have engendered undue optimism and encouraged the tendency to forget that the real test of evacuation has yet to come. The problem of dispersal, however urgent as a first step in national defence, is simple compared with the more abiding social problems which evacuation presents, not only under emergency conditions but also in the permanent re-integration of national life.

It is well to recall at the start that, as Dr. T. Adams pointed out in his able paper at the British Association meeting at Dundee, under certain conditions, evacuation, however difficult and costly, must remain for some few cities an indispensable element of defence while the possibility of war remains, unless we are prepared deliberately to forgo certain of the advantages which can only be realized in a properly administered city. Accordingly it is important that the experience gained at every stage from the actual preparation and conduct of the evacuation, to arrival and settlement in the reception areas, the social problems of the evacuated areas, until the final return to and re-settlement in the evacuated areas when the emergency has passed should be carefully sifted and studied by scientific and impartial minds.

The outstanding feature of evacuation in England is indeed that it is a social experiment on a very large scale, and its success or failure will depend on the attention which is given to the social factors, and the thoroughness and impartiality with which they are investigated and handled. It should be obvious that many of the well-founded complaints which are encountered arise primarily from neglect of, or imperfect attention to, social factors in the preparation for the dispersal. Certain misfits or embarrassments were almost inseparable from a domestic re-shuffle on the existing scale. Differences of outlook and of social position must be expected and should provide no insuperable bar to domestic harmony. Different conceptions of what constitutes personal cleanliness present much more intolerable difficulties, and complaints on this score have come as freely from those acting as hosts as from evacuees who shrink from the squalor of the homes in which they have been placed.

The extent to which such complaints have been voiced is clear evidence that something has been seriously amiss with the planning of the evacuation. Insufficient attention has been paid to the relative social types of evacuating and receiving areas. In some instances accommodation of the exact type required has been untapped while the evacuees were received into neighbouring districts under conditions which promptly stimulated a migration homewards. The veriest attempt at social survey or comparison of receiving and evacuating areas would have greatly reduced the proportion of misfits.

It should not, of course, be too late to remedy the worst mistakes, and indeed certain education authorities have taken wise and effective action. Too much stress cannot be laid on the importance alike of checking any homeward drift and of encouraging the good will between the evacuees and their hosts which is generally so conspicuous a feature. The value of this sympathy and understanding can scarcely be overstressed in relation to the social re-integration which lies ahead.

That is the aspect upon which attention should next be concentrated, and the reopening of the schools and development of the educational organization in the reception areas is only a special aspect of this problem. Difficulties raised by such questions as equipment and buildings are of secondary importance compared with that of ensuring that the evacuated children are living in a background favourable to their development, and repairing so far as possible the damage which upheaval and separation from homes and parents and familiar surroundings may have engendered.

If it is necessary to plan for a period of three years or more, as indicated by the Government, something more than temporary expedients will be required, whether in regard to educational equipment or social background. Moreover, the drawbacks of improvisation in teaching are all the greater if the satisfaction and support which the normal home surroundings afford are lacking. Equally the social services which the development of education has been rendering may be even more imperative under the conditions which obtain in the reception areas if the nation's capital in youth is not to be wasted.

To maintain existing standards of education and well-being among children and adolescents in the conditions imposed by evacuation is no simple problem, but its solution is essential, and no exigencies of national defence can justify its neglect. Indeed, the experience of the War of 1914-18 should remind us of the danger of abandoning policies already laid down for improving those standards. It is not to be expected that no checks will be encountered or no harm done under the conditions of strain and hazard imposed on the whole nation; but there is no more vital national interest than that of seeing that the young are shielded from any untoward effects so far as possible, and the disturbance of their normal development and training minimized.

The educational problem is only one of the issues raised by evacuation, and even here there are features which may yet prove to be assets. To thousands of children from congested areas and slums a new world is opening, and the spirit of adventure in which they set out at least holds promise of an opportunity of bringing townsfolk to learn something more of the countryside and of its life which could give a new meaning to some of the content of educational syllabuses. The spirit in which most people in the reception areas have accepted their responsibilities and the courage and adaptability of most adult evacuees are other solid assets that have not only made the evacuation scheme workable but also helped to alleviate the wholesale disruption of family life entailed.

The opportunity of social re-integration must not be missed, and the good will displayed in the actual evacuation cannot be allowed to be dissipated. Steps must be taken to mitigate and to eliminate the disruption of family life so far as possible and to explore rapidly all avenues, such as the construction of rural camps which offer the prospect of terminating the separation of mothers and children. Besides this, problems of health and hygiene will demand close attention if the dangers of epidemics, especially under the stress of emergency conditions, are to be prevented or minimized, and excessive strain on health, sanitation, water supply and other public services in the reception areas avoided.

Many of these matters call for wise planning and scientific investigation; but no complete solution can be achieved if we fail to remember that the problem is a national one and not merely that of a number of independent reception areas. The evacuated areas themselves will be subjected to economic and social stress and strain even if fortunately spared from actual attack from the air. Not merely private households, but also general trading conditions, amenities and public services cannot but be profoundly affected if not dislocated by the removal of a high proportion of the population of an area.

The economic problems of evacuation are large and complex. No less important are those of recreation and fitness. These reach far beyond the provision of facilities for organized games for the schools in the reception areas. The existence of amenities for physical and mental refreshment is a vital factor in the psychological adjustments involved and in the maintenance of morale.

The psychological aspects of evacuation are possibly the most important of all. Neglect of them may delay the establishment of reasonably satisfactory conditions in reception and in evacuated areas. At the worst it may lead to deterioration in morale, which by frustrating the very purpose of evacuation may endanger the whole national effort. The stresses set up both in evacuation and in reception areas, like those caused through the whole fabric of civil life by the necessity of re-adapting or even re-orientating life to the restrictions of movement, lighting, etc., imposed by wartime exigencies, and the strain of long hours, often with responsibilities in some branch of civil defence in addition to the working day, demand some opportunity for relief from time to time if serious physical or psychological damage is not to result.

On this ground alone the question of recreation presents problems which cannot long be neglected. Means must be found, consistent with public safety, of ensuring reasonable opportunities of entertainment and relaxation. Possibly the transfer or redistribution of such facilities in the reception areas may be involved as part of the policy of developing an adequate communal life. It should not be forgotten, however, that the migration to the reception areas has, together with the curtailment of public and private means of transport, largely closed for purposes of recreation areas which derive most of their importance from their value as health resorts. As the war continues, the need for attention to such questions cannot but increase.

These are only some of the more immediate problems which evacuation presents. There are others equally important which will require attention before the normal trend of the national life can be resumed. The dispersal of business and industrial firms as well as of Government departments and the accompanying decentralization will raise questions of policy before a return can be made to previous locations. New and unexpected opportunities of town planning and of guiding the location of industry may well present themselves, if the experience now being gained is wisely utilized. In these, as in the more immediate and pressing problems, impartial survey and patient scientific investigation of the many economic, social, technical and psychological factors involved are essential. Scientific workers would be unworthy of their own traditions if they failed to insist on the importance of a scientific study of the problems which evacuation presents, or to direct attention to factors which threaten to sap either the physical or the moral welfare of the nation in the task to which it is now addressed.

FLUID DYNAMICS

Modern Developments in Fluid Dynamics
An Account of Theory and Experiment relating to Boundary Layers, Turbulent Motion and Wakes. Composed by the Fluid Motion Panel of the Aeronautical Research Committee and others, and edited by S. Goldstein. (Oxford Engineering Science Series.) Vol. 1. Pp. xxiv + 330 + 29 plates. Vol. 2. Pp. xii + 331–702 + plates 30–35. (Oxford: Clarendon Press; London: Oxford University Press, 1938.) 50*s*. net.

THE present work is dedicated to the memory of Horace Lamb, the father of classical dynamics, whose fundamental work, "A Treatise of the Mathematical Theory of the Motion of Fluids", appeared in six English editions as well as in several foreign translations and is in the hands of every specialist in the theory of fluid motion. By 'classical' hydrodynamics, we understand the hydrodynamics of the nineteenth century in contrast to that of the twentieth, which is distinguished chiefly by a more detailed and at the same time extensive study of the influence of viscosity, particularly in the case of fluids of small viscosity, so that a much nearer approach to reality has been attained. Even those parts of the modern theory which are fundamental for the ideal frictionless fluid have been enriched in very important points by new research. Here, the knowledge of the existence and behaviour of surfaces of separation was effective in the discovery of new ways in which to obtain practical results.

During the last twenty years, much new knowledge, with practical applications, has matured concerning the disturbance occurring in the majority of technical fluids—of which the ultimate cause is still a problem—which is known as turbulence. These developments have proved extremely fruitful where scientific application is concerned, as, for example, in meteorology and oceanography.

The great interest which has developed in recent years in aeronautical science, for which fluid theory is of basic importance, had considerable influence on the rapidity of progress in the science of hydrodynamics. In consequence, research in the subject has advanced at such a pace and has given rise to such an immense literary output, that it has become increasingly difficult for any one individual to keep up with it. Hence a number of works of a co-operative nature have appeared in which the attempt is made to present a survey of all the results obtained by research. Two earlier works of this kind are "Handbuch der Physik", Vol. 8 (1927), by Geiger and Scheel, and "Handbuch der Experimentalphysik, Vol. 4 (I–IV, 4 (1930–1932)). A newer work in six volumes, entirely devoted to aerodynamics, is "Aerodynamic Theory" (1934–1936), by W. F. Durand.

Although the present work is distinguished from previous ones by its intentional limitation to particular fields which are intimately connected with one another, the sections in themselves are amazingly comprehensive. For this reason alone, the book is certain to remain for a long time indispensable to the further development of research in these fields. A characteristic of the whole domain with which this book is concerned is that it includes those branches of hydrodynamics and aerodynamics which are concerned with viscous fluids and particularly those possessing low viscosity, or, in other words, with laminar and turbulent flow, with special consideration for flow near the surfaces of solid bodies and in the domain of great turbulence behind them. Furthermore, the transference of heat in laminar and turbulent fluid motion is considered. On the other hand, neither potential fluid motion, nor the three-dimensional aerofoil theory, nor the propeller theory are dealt with. Nor indeed do the problems of compressibility and cavitation come under consideration.

The contributors to this work include members of the Fluid Motion Panel of the Aeronautical Research Committee, of which Sir Horace Lamb was a member for many years and which now includes eleven British research workers and four younger workers. It is a truly co-operative work in which even the names of the authors are kept well in the background. In fact the only name which appears is that of the editor, Dr. S. Goldstein, who directed the research and writes an introduction for the benefit of the reader, in which the most important concepts in hydrodynamics are expounded in a brief but extraordinarily clear manner.

The contents of the book are arranged as follows. Of two introductory sections, the first is concerned with fundamental concepts and with the laws of motion of the ideal non-viscous fluid, and the second with laminar and turbulent boundary layers and their effect with regard to drag. In the third section, a strict mathematically formulated account of the laws of viscous fluids accompanied by accurate solutions of the equations is given. The fourth section expounds the mathematical theory of fluid boundary layers, the fifth is devoted to the concept of turbulence, while the sixth discusses experimental apparatus of all kinds (wind tunnels, experimental tanks, whirling arms, velocity and pressure measurements, visualization of fluid motion). In the seventh section as well as in the eighth, with which the second volume begins, fluid motion in pipes and canals and along level plates, obedience to the law of the laminar and turbulent forms of motion together with the relation of the former to the latter, are very thoroughly expounded In Section ix the problem of resistance in the case of symmetrical cylinders is discussed, while Section x is concerned with the resistance of asymmetrical cylinders and special aero-foils; in Section xi rotation shapes (airship shapes) are considered. The different kinds of control of boundary layers are examined in a further section, which is followed by another to consider events taking place in the wake of a moving object. The final sections, xiv and xv, are concerned with heat transfer by conduction and convection in laminar and turbulent fluid motion.

The excellent illustrations are a special feature of the work. Wherever possible they are taken from original monographs, and the photographs—the majority from the original—are excellent half-tone prints reproduced in thirty-five plates. This natural documentation increases the interest of the book and is very welcome. Furthermore, the value of the work, which is carried out most conscientiously in all sections, is much enhanced by very complete author and subject indexes covering twenty-two pages. The reviewer noted with great appreciation that not only important English works on the subject, but also all those known to him in the foreign literature also are included. There is no doubt that this work will contribute enormously to the furtherance of research in the subjects with which it deals and that it will be of inestimable use to students.

The reviewer would like to make one suggestion, namely, that short explanatory legends under the illustrations—which are absent in this work—are very helpful to those who have not studied the text of the book itself. Such explanatory legends are particularly helpful when one is glancing through the book for the first time. L. P.

SYMBIOSIS BETWEEN FUNGI AND SCALE INSECTS

The Genus Septobasidium
By Prof. John N. Couch. Pp. ix + 480 + 114 plates. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1938.) 5 dollars.

UNDER the able leadership of Prof. W. C. Coker, the Botanical Department of the University of North Carolina has produced several major works on fungi: "The Saprolegniaceæ, with Notes on other Water Molds" (1923); "The Clavarias of the United States and Canada" (1923); "The Gastromycetes of the Eastern United States and Canada" (1928); and "Studies of the Genus Pythium" (1931). To these there has recently been added John N. Couch's splendid monograph on the genus Septobasidium.

By means of sucking tubes, scale insects obtain their nutriment from the cambial region of the plants to which they become attached. Von Hörnel and Litschauer in 1907 were the first to direct attention to the remarkable fact that, in the dried species of Septobasidium investigated by them, scale insects are always present under the hyphal mats formed upon the bark of twigs or branches. Couch, working for more than ten years on living material, has now shown that scale insects are present in the hyphal mats of Septobasidium species in general and that the fungi and the insects live together symbiotically. A Septobasidium can extend its development only in connexion with scale insects, and when these insects die the growth of the fungus ceases. The insects are protected from their enemies by the fungus, and the fungus draws its nutriment from, and is distributed by, the insects. The symbiotic relationship of the fungi and their associated insects has been discussed by Couch in detail.

In *Septobasidium Burtii*, the life-history of which Couch describes and illustrates very fully, the fungus mat above an insect's body on an oak branch is nowhere in direct contact with the insect, but the two are connected together by numerous coiled hyphæ. This arrangement gives the insect freedom of movement to breathe, so that it will not suffocate. The coiled hyphæ are attached to the insect at the dermal pores and setæ. By means of the threads passing through the natural apertures of the insect's body-wall the haustoria of the fungus within the insect's body are connected with the mat and thence with the other parts of the fungus. The haustoria are found only in the circulatory system or hæmocœl of the insect, and they are coiled in form.

With the help of the haustoria, the fungus obtains the nutriment necessary for its growth and for the production of basidiospores on its exterior surface. Not all the insects beneath a stroma are parasitized, but those that are are dwarfed and incapable of reproduction. The young insects are infected by bud cells formed by the spores and never by fungal hyphæ. Some of the insects which have become infected by crawling over the spore-bearing surface may crawl back beneath the fungus colony under which they were born, others may settle down beneath other fungus colonies, and some settle down on the bare bark. The first two groups of insects are solely responsible for the survival and continued growth of fungus colonies, while the third group, which settle down on clean bark, are solely responsible for the distribution of the fungus. Under natural conditions, whereas the fungus cannot live without the insects, the insects are able to live without the fungus; but the life of insects unprotected by the fungus is precarious.

Septobasidium is widely distributed in the world. There are numerous species in the United States, the West Indies, Brazil, Ceylon, Java, and the Philippine Islands, and a few species have been found in Europe and Australia.

By far the larger part of the volume is devoted to taxonomy. On the basis of the symbiotic relationship, Couch has raised the Septobasidiaceæ to the rank of an order, the *Septobasidiales*, coordinate with the Auriculariales, the Uredinales, and the Ustilaginales. A key for identification is followed by a description of 163 species, 5 varieties, and 2 hybrids. Some 56 species are described as new.

The illustrations are numerous and admirable. Among other things they depict: the insect houses and their occupants; the relations of the fungi and insects with one another and with the tree at the expense of which they both ultimately live; the ways in which the fungi extend their colonies by the capture and infection of more and more young insects; and the microscopic details of structure of nearly all the species of Septobasidium which have been described.

Prof. Couch is to be heartily congratulated on the outcome of his labours. By long-continued and exact observation he has added greatly to our knowledge of Septobasidium species, and at the same time he has made a series of beautiful discoveries concerning the relations of fungi and insects. His book is a valuable addition to biological literature, and its contents will appeal not only to mycologists but also to entomologists and naturalists in general. A. H. REGINALD BULLER.

SPECTROSCOPY IN INDUSTRY

Spectrographic Analysis in Great Britain
Edited by A. C. Candler. Pp. 80. (London: Adam Hilger, Ltd., 1939.) 7*s*. 6*d*. net.

MODERN spectrographs suitable for industrial work originated in Great Britain nearly thirty years ago, and their application to industry has been continuously increasing for three main reasons. First, for purely routine control, the spectrographic method is often much more rapid than a purely chemical one and, moreover, may require fewer workers. Secondly, chemical analysis may be less reliable when the estimation of mere traces of certain elements is involved. Finally, only small quantities of material are required for spectrographic analysis.

The monograph under consideration comprises twenty-eight articles describing the application of spectroscopic methods to a wide range of subjects, including analysis of alloys, detection of metallic contamination of beers, agricultural problems, archæology, and last, but by no means least, to forensic science. All the articles are brief.

The spectrograph, for example, has proved helpful in tracking down the causes of obscure diseases of crops and stock. Thus teart, to which cattle in certain areas are subject, is found to be associated with an increased molybdenum content in the herbage. In view of the minute traces of molybdenum involved, a long time would undoubtedly have elapsed before this discovery could have been made, had chemical methods alone been available.

The concluding article, which deals with forensic science, suggests numerous ways in which the spectroscope can assist in tracking the criminal. Thus counterfeit coins may be compared with dust from the suspect's pockets; a fragment of glass from the turn-up of a suspect's trousers may be compared with the glass of a window broken in a smash and grab raid.

The monograph may be recommended to all interested in the application of spectroscopy to almost every walk of life.

J. NEWTON FRIEND.

THE FACTORS OF THE MIND

The Factorial Analysis of Human Ability
By Prof. Godfrey H. Thomson. Pp. xv + 326. (London: University of London Press, Ltd., 1939.) 16*s*. net.

MOST psychologists have assumed that all mental activities are reducible to a small number of independent 'factors', such as intelligence, emotionality, verbal capacity, manual capacity, introversion or its opposite, and the like. Prof. Thomson's book is concerned, not so much with discovering what these factors may be, but rather with a critical examination of the mathematical procedure by which, it has been claimed, their existence may be established.

The older 'faculty school' simply postulated such elementary capacities as they were required; the newer school of statistical psychology supposes that they can be deduced mathematically by analysing correlations between test-performances or estimates of character. Various methods have been devised for this purpose—all loosely covered by the broad term 'factor analysis'. Of these the earliest was Prof. C. Spearman's well-known attempt to demonstrate that all mental processes involve a single intellectual factor, identifiable with 'general intelligence'. His formulæ assumed that two factors only were sufficient to account for every test performance. Later work in Great Britain, particularly in the field of educational testing, indicated that more specialized factors (verbal capacity, arithmetical capacity, etc.) appeared to enter into different tests, in addition to the 'specific factor' peculiar to each one and the 'general factor' common to all. The notion of multiple factors, as a substitute for that of dual factors, has since found strong support in America; and recent workers have endeavoured in various ways to generalize the simpler theorems of the two-factor hypothesis to meet these wider needs.

In the book under notice, Prof. Thomson brings together into a single clear and systematic exposition all the chief factorial methods that have hitherto been put forward. He explains their mathematical derivation in an elementary way for the student of psychology, and briefly compares their merits and their disadvantages. He also incorporates a summary of his own very valuable contributions, including more particularly a revised version of the sampling theory which he had put forward as an alternative to the two-factor theory of Prof. Spearman. From the first page to the last the treatment is remarkably lucid, suggestive, and impartial.

Prof. Thomson claims that his book is written primarily for the reader "with little or no mathematical knowledge beyond what is ordinarily imparted in the secondary school". Nevertheless, even the professional psychologist and statistician will welcome the compendium of formulæ and proofs brought together in the mathematical appendix, and throughout the book will find new light continually shed on old problems. In common with most recent contributors to the subject, Prof. Thomson believes that these problems are best solved by matrix algebra; and, in their abstract form, the solutions reached are, as a matter of fact, often strikingly similar to results independently obtained by quantum physicists. But, as the present reviewer has more than once pointed out, although these methods were originally developed for the analysis of the results of psychological testing, they would be almost equally applicable to the solution of analogous problems in many other fields—in physiology, biology, sociology, medicine, economics, agriculture and, indeed, in almost any science where causal factors are numerous and inextricably interlinked. The book must at once take its place as one of the most important publications of the year in the field of education and psychology; at the same time it should be of great interest to all who are engaged on statistical research, no matter what their special sphere.

C. B.

TABLES FOR STATISTICIANS

Statistical Tables for Biological Agricultural and Medical Research

By Prof. R. A. Fisher and F. Yates. Pp. viii+90. (London and Edinburgh: Oliver and Boyd, 1938.) 12*s*. 6*d*. net.

MODERN statistical analysis, particularly that relating to the production of adequate and exact tests of significance, owes much to the painstaking researches of R. A. Fisher, whose text-book, "Statistical Methods for Research Workers", has gone through a number of editions since it was first published in 1925. Not the least valuable feature of this work is the collection of tables, which have proved so indispensable to the statistical worker of to-day that they have been repeatedly referred to, and in certain cases reprinted, through the generosity of author and publisher. The desirability of having them separately published has been felt in many quarters, and in the volume now before us we have a work in which the tables of Fisher's book have been not only reprinted but also amplified, and many other tables have been added. While not a complete manual of statistical tables, available for all purposes (it is not, for example, very easy to fit a normal curve from the tables provided), the book is a very useful collection, and should be the indispensable companion of every statistician.

The first set of tables consists of those from Fisher's book, considerably extended (especially as to the z-table and its accompanying "variance ratio"), and with two new tables. The second set consists of tables of probits and angular transformations, found useful in medical research. We then come to a section of non-numerical tables, lists of Latin squares, and combinatorial solutions required for the design of balanced incomplete blocks—a set of tables which should be very useful to the agricultural experimenter. Following this are tables of a more miscellaneous character, including an interesting and useful new table of orthogonal polynomials, which should much simplify the calculations in problems of fitting curves. Finally, to complete the set, we have tables of logarithms, including natural logarithms up to 100, squares, square roots, etc., and tables of certain trigonometric functions. The last is a new table of random numbers.

As an example of mathematical table construction the work is excellent. The printing, spacing and presentation, and the large flat page, are according to the best canons. Where interpolation is necessary, the tables are adequate for the purpose, and the methods to be used are stated. In the case of standard tables, with mean differences, there is the interesting innovation of providing mean differences for half the interval only, thus teaching the user to subtract as well as add, and making for greater accuracy in the final result. The introduction, as is to be expected, has points of originality and interest, and is in itself a worthy piece of mathematical research. While some readers may be disappointed by not having standard uses of the standard tables illustrated, they will on the other hand welcome new statistical tests there described, together with suggested new uses of old tables, and the ways of using effectively the new tables.

J. Wishart.

PERSPECTIVES IN EVOLUTION*

By Prof. J. Ritchie

University of Edinburgh

"ALL useless science is an empty boast," Shakespeare is alleged to have said, but he lived before that pernicious cleavage had been made between pure science and economic science, which suggests, as Hinton once said, that the latter is a gold-digger while the former excavates only knowledge. And while we are strongly in favour of those lines of scientific endeavour which make their first purpose an attack upon the evils that man and his possessions fall heir to in the course of Nature, and which aim at easing the human struggle for existence, there are questions of no immediate practical moment to which the inquiring spirit of humanity demands an answer. I do not think Shakespeare would have called these recurrent problems "useless science", for the mind of man requires satisfaction as well as his material need.

The Secret of Life

Much that was mysterious about life has disappeared or is disappearing before the persistent inquiries of the physicist and chemist. Life processes of the physiological order are ruled and guided by the self-same laws which regulate action in the non-living world.

But it is just as obvious that none of these interpretations reaches the secret spring of life itself. The physical explanation of the architecture of animals must assume the power of the living thing to react and mould itself to the forces that play upon it. The Donnan equilibrium, which interprets a condition of thermodynamical balance, meets the case of a living cell only when the cell activity is at its lowest, and the more active, that is the more alive, a cell is, the less does the Donnan theory become applicable Enzymes may be necessary for the complete activity of a cell, but, though it may hasten a chemical reaction, no catalyst can set a reaction in motion; in the case of the cell that appears to be the prerogative of 'life'.

Let us turn, then, from the minute analysis of the unit of life which in recent years has done so much to reduce the mystery of life, without, however, reaching the kernel of the mystery, to see what suggestion may arise from another point of view, a perspective of evolutionary processes.

The occurrence of certain organic aggregates on land and in the ocean, and the increase in orderly arrangement of matter revealed in the evolution of life from more simple to more complex, leads to the conclusion that in practice the second law of thermodynamics, so well established for physical happenings, cannot be satisfactorily applied to living processes; and that while no one would deny that living things in the long run and in a universal sense are subject to its demands, and indeed that in their workings they are probably controlled by it, nevertheless organisms *appear* to be able temporarily to hold up or withstand the physical course of degradation of matter, if they do not actually reverse it.

From this point of view, then, the secret of the living organism, that is its essential difference from non-living matter, is its power of trading with its environment in such a way that it can build up its body stores of high potential energy from materials of lower potential.

Phenomena of life elude treatment by the laws of thermodynamics, not necessarily because living matter does not obey these laws, but because the unknown conditioning of working organisms is too complex to yield to analysis applicable to inorganic states. Nor does it seem likely, since livingness exists within a very limited range of temperature and is readily extinguished by interferences, that it can ever be subjected to the sort of analysis which has led to the interpretation of the constitution of physical matter. It seems logical, therefore, to take as axiomatic the existence of life, not as a vital force which animates something different, namely matter, but as the activity of an atomic combination the very activity of which renders it unanalysable by the standard methods of the physicist and chemist. Thus, as one of the greatest of living physicists, Niels Bohr, has pointed out, the biologist would accept for the living world a position analogous to that accepted by the physicist for the non-living. "The existence of life must be considered as an elementary fact that cannot be explained, but must be taken as a starting-point in biology, as in a similar way the quantum of action, which appears as an irrational element from the point of view of mechanical physics, taken together with the existence of the elementary particles, forms the foundation of atomic physics."

The biologist, admitting 'life', may build up a whole body of biological theory, as distinctive and peculiarly his own, and as logical in the logic of probability which Professor Darwin advocates, as are the theories of the physicist or the chemist in their own limited fields.

---

* From the presidential address before Section D (Zoology) of the British Association, delivered at Dundee on August 31.

Lengthening of Life Perspective

There is another notable development of this century which must affect evolutionary thought, the expanding idea of the time during which the earth and life upon the earth have been in existence.

From the earlier discussions it would appear that a psychological element entered into the final estimates, as if the calculators drew back aghast at the possibility of the enormous age of the earth at which their estimates hinted. Thus almost all tended in their final summing towards the minimum of their scales, and little is heard of the other extreme—Lord Kelvin's independent maxima, reached by different methods, of 1,000, 400 and 500 million years, or Geikie's 400 million years—although these came much nearer to the modern estimate.

Now, a consensus of opinion admits credibility to estimates based upon the break-up of radioactive minerals in the rocks. We may say that life has existed upon the earth for perhaps 1,200 millions of years; and then to complete the picture that the birth of the earth and, as the new cosmology seems to indicate, perhaps also at the same time the stupendous birth of sun and stars, took place about 2,000 million years ago.

Stability of Organism and Slowness of Evolution

This amazing extension of the time concept of life emphasizes anew some of the striking features of evolution. We are accustomed to lay stress on the variation of living things, upon which evolution depends, but surely more remarkable is the stability of living organisms, which retain their own characters in spite of changes in the environment, and whose germ cells pass these characters unaltered through countless generations. The edible mussel (*Cardium edule*) has retained its specific characters for two million years or more; its genus, in a wide sense, lived 160 million years ago in the Trias. The Crinoid genus Antedon which flourishes in our own seas antedated that old bird Archæopteryx in the Jurassic Period, 140 million years ago. It is surprising enough to realize that genera of foraminifera, like Nodosaria (Silurian) and Saccammina (Ordovician), still abundant in our oceans, have retained their generic characters for about 300 million years. But they are relatively simple organisms; it is still more astonishing to think that contemporaneous with them or before them lived modern genera (again in the wide sense) of more highly organized brachipods, like Lingula (Ordovician) and Crania (Ordovician), and that these have experienced the geological upheavals and secular changes since Palæozoic times without turning a hair, or, in the revised version, without the shift of a gene upon a chromosome.

It is in agreement with that stability of organisms that we must conceive of evolution as a process of extreme slowness, as if living things are loth to change, and ultimately change only under the direct compulsion of circumstances. Of that slow progress in its minor phases the new chronology gives us a measure.

If this time-factor is a necessary element in the evolution of species in Nature, doubt is thrown upon the validity of arguments concerning evolution based upon laboratory experiments, in which intensification of means produces rapid change. There is no reason why the reaction of an organism under such exaggerated stimuli should be the same as that produced by minimal influences of the same nature over an exceedingly long time. Even in inorganic Nature the reaction of inanimate environment may differ according to the time element. The sensitive organism delicately adjusted to a particular environment is less likely than inorganic environment to give a 'natural' answer under concentrated compulsion.

Advent of Man and Evolution

The lengthening of the time perspective of life upon the earth adds new insignificance to the span of man's tenancy of the world and new impressiveness to the part he has played as an agent in evolutionary processes. Man of our own genus, beginning in the early Pleistocene Period, has probably less than a million years behind him, but the species of man now dominant in the world (*Homo sapiens*) appeared only at the close of the Würm Glacial stage, no longer than 25,000 to 40,000 years ago. Yet even this relatively short space of time exceeds man's span as an effective agent in world change, for in spite of the arts he developed in early post-glacial times he remained practically submerged in the fauna, having little more influence upon his environment than the beasts with which he shared it.

It was Neolithic man who set the ball a-rolling through his outstanding achievements in domesticating wild animals and in developing the cultivation of the soil and the growing of crops. For these achievements, apart from laying the foundation of a new era in the progress of civilization, started a series of changes which have profoundly influenced the distribution of life upon the earth. In one direction the safety of flocks and herds demanded the elimination of beasts and birds which threatened them, and in another the need of land for crops and pasturage played havoc with the wild environment and so with the fauna which it sustained and sheltered, although the crops themselves encouraged the multiplication of certain elements in the fauna which became the pests of agriculture.

The Neolithic Age, which originated these changes, reached Western Europe only some 8,000 years B.C., though in the East and in the lands of old culture it began several thousands of years earlier. But Neolithic man, although he initiated the most far-reaching changes in plant and animal life, was himself, with his implements of wood and stone and limited powers of offence, ineffective in his interference. Even in a limited area like Scotland, few animals died out during his rule and it would be difficult to bring home to him responsibility for their disappearance. For the effective introduction of man as an agent of evolutionary change we must look to a time more recent. And that time is determined by his increasing efficiency as a cultivator and destroyer, and particularly by the need for food and fire demanded by an increasing population. These influences began to make their mark about the tenth century of our era, when several of the interesting members of the primeval fauna of Great Britain had disappeared or were on the verge of extinction, but in the centuries following the sixteenth they commenced a period of pressure, which, increasing in intensity, has transformed the faunas of civilized lands.

It is not an accident that the emergence of man as a major factor in the evolution of faunas coincided with the increased power of destruction presented to him by the invention of gunpowder and guns, and with that extraordinary increase in population which in the last three hundred years has multiplied, almost five times over, the numbers of mankind upon the earth. For this burst of population was itself the accompaniment of intensified agriculture and stock-rearing, of the spread of industries and development of commerce, all of which have had profound repercussions upon aboriginal faunas and floras.

While modern man has existed upon the earth for some 30,000 years, his part as a distinctive agent in the evolution of faunas is limited to a thousand years, and within that span his great transformations are practically confined to the last three hundred years. That is a period infinitesimally short compared with the ages during which the aboriginal faunas into which he was launched had been differentiating, redistributing and establishing themselves in a natural balance. What transformations has he wrought in so short a time ?

I do not propose here to examine in detail the magnitude of this new world factor in the evolution of faunas and floras. That is best shown in a limited area which can be intensively studied, and I have elsewhere described with reasonable thoroughness the stages and sum-total of this process in Scotland, the recent geological history of which makes it particularly suited for such an analysis

I may, however, indicate the depth of penetration of this new faunistic factor by pointing out how superficial is the view that regards man merely or mainly as a destroyer. He has indeed deliberately reduced numbers or extirpated animals for his own protection or for that of his flocks and crops, for food and other necessities, for sport, and to satisfy the whims of luxury ; and without intention his cultivation of plains and marshes and destruction of primeval forest have destroyed feeding grounds and banished their former tenants. Yet his addition to numbers far outweighs his destruction. Intensive cultivation has added a stock of domestic animals far beyond the bearing capacity of wild country, besides increasing the numbers of wild creatures which also benefit from his crops. Deliberate protection of animals, for sport, for utility, for æsthetic reasons, and on account of popular superstition, has also multiplied numbers. Furthermore, apart from numerical changes within the aboriginal faunas, man has changed their qualitative composition by introducing foreign animals deliberately (here we must include domestic animals), and unintentionally through the ramifications of international commerce.

These are simple primary effects of man's interference ; secondary and remote consequences are even more impressive in their ultimate issues. In general it may be said that, wherever civilization has made itself felt, three main faunal changes are noticeable : the largest animals tend to be reduced in numbers and eventually to disappear ; smaller creatures, dependent upon cultivation and human habitations, multiply far beyond aboriginal numbers ; and the deliberate or accidental spread of 'foreign' creatures is creating a degree of cosmopolitanism throughout the world's faunas.

How do these changes brought about by man stand, viewed in the perspective of the long evolution of faunas upon the earth ? There are two types of change in progress in the natural assemblage of animals in any region. There is a constant ebb and flow within the fauna itself due to local and temporary influences, a swing of the pendulum about a mean, the 'balance of life' which is never quite struck. But there is also a faunal drift, revealed in the story of the rocks or in any long vista of faunal history, and this is due to great secular changes, to geological influences, to modifications of climate, to the insurgence of the forces of life.

Where man's interference is temporary and casual it may be compared to the internal faunal tide, which is of little moment in the long run ;

but where his interference is persistent in any direction it must be reckoned as sharing with the great secular forces of Nature in propelling a fauna upon a path along which there is no return.

Such is the remarkable conclusion to which the long view of man's place as a natural agent brings us—that he has set in motion forces which, in our era and mainly in the last three hundred years, have wrought faunal changes which can be compared only with the great secular changes of world evolution. When the ridiculously short span of his interference is contrasted with the slowness of natural processes, the probability forces itself upon us that in a few more thousand years of man's inheritance of the earth the old order of Nature will be superseded in the faunas of the world by a new order of mankind.

MAN IN EVOLUTIONARY PERSPECTIVE

Having thus assigned to man dominance among the forces which determine faunal assemblages, let me now endeavour to put him in his place in the long perspective of life and evolution.

Many have speculated upon the new view of man's future. To some it has seemed likely that future progress will be along the lines of individual development, that brains and mind will become more perfect in their working until man is master of all Nature. Others look to a future in which not the individual as a unit, but society as an integration of individuals will become more closely knit and more perfect in its functioning.

Still others see in the modern developments and threats of warfare a warning finger of the doom of civilization. I would remind these doubters that evolution as we know it is built upon destruction; that the development of the whole animal kingdom rests upon the destruction of green plants, which biologically are formed of the same stuff as we are, and that within the animal kingdom the flesh-eaters have risen upon the bodies of their fellow-creatures. The drama of wars amongst mankind and the imminence of war seizes the imagination, and history-books bias the mind by emphasizing wars and ignoring the quiet but effective work of millions of unknown citizens through the ages. But in our perspective of hundreds of millions of years these are the merest incidents and, war or no war, the quiet progress of evolution flows through life carrying the world of living things steadily but unobtrusively from one step to a higher.

In his short past man has been moving towards a higher intellectual, spiritual and moral standard, and the biological view would be that in the immediate future (geologically speaking) that movement will continue, and that for human beings this future lies in the development and perfection of social life and in the spreading of the social idea to include peoples and nations as well as individuals, with all the correlated advances that these imply.

That is the short view of man's future, but what of the long view of mankind upon the earth? I notice that Sir James Jeans contemplates, at any rate fancifully, the existence and progress of humanity until the shadow of the extinction of life upon the earth falls upon the world, many millions of years hence. Does our vista of life support such a view? We must admit that any view of science about the future of humanity can be only a short-range forecast; of the long-range forecast it can say nothing. The reason is that science knows only the past and the present, so that it can read into the future only the glorification or degradation of what has already been expressed in mankind, let us say better brains, better social organization, less self-seeking. Yet the unfathomable characteristic of life is that it is always throwing up something new; evolution proceeds not only by permutations and combinations of the old, but by the emergence of new lines of development. The physicist can foretell with accuracy the movements of the planets, the return of eclipses and comets, but who, knowing only fishes, could have foretold the amphibia which arose from them, or, knowing only the reptiles, could have foretold their descendants the birds and the mammals? When we leave details in the world of living things we can be wise only after the event; we cannot be wise before the event. Therefore the long future of evolution upon the earth is unknowable, so far as science is concerned.

Nevertheless, bearing that warning in mind, we may gain some hint from our perspective of life upon the earth.

We look upon man, and rightly so, as the crowning glory of evolution: stage by stage, we say, the evolution of the past has led up to him; we can imagine nothing higher, evolution appears to have reached its goal.

But step back some 180 million years in our time-scale to the Triassic period when the great dinosaurs dominated the earth and nothing higher than reptiles had been evolved. To themselves and to the creatures which shared the world with them, they must have seemed (if they had any self-consciousness), and indeed they were, the crowning glory of creation; stage by stage the evolution of the past had led up to them; nothing higher could be imagined, evolution appeared to have reached its goal. That could be said by their contemporaries of the highest creatures at every stage in the course of 1,200 million years of evolution, just as it is said of man to-day. A hundred million years have rolled past since the time of the dinosaurs, and they and all their immediate kin have disappeared for ever, and new and unforeseen trends of life have blossomed, as they have done over and over again, and have carried the story of evolution on to the present, when man is the dominant and highest.

Looking back over that 1,200-million-year vista of the steady climb of life upon the path of evolution, it seems presumptuous for us to suppose that man, the latest newcomer, is the last word or the final crowning glory amongst many, and that with his coming the great steps in evolution have come to an end. Looking forward to the future of life upon the earth, it seems even more presumptuous for us to suppose that for the next 1,000 million years life, so surprisingly inventive in the past, should be tied for all time to come to trifling changes like increase of brain power or better social organization for mankind.

The truth is that we, bound by the past, can imagine nothing more, but if the long vista of evolution is any clue to the future, we cannot regard mankind, the crowning glory of the present, to be more than a stage in life's progress and a milestone upon the path of evolution towards a greater future. To think otherwise is to imagine that with the coming of man, so insignificant in time, the advance and inventiveness of evolution, steadily carried on through an unimaginable vista of years in which no trace of slackening can be perceived, has all but come to an end.

It may seem to you that our perspectives have carried us far afield into a future so remote that it is scarcely worthy of consideration. My excuse must be that we are so accustomed to think of man as the sole significant inhabitant of the world that it is worth while now and again to look upon him in his biological setting as but one, and yet so far the greatest, of the manifestations of life upon the earth.

THE FUTURE OF FLYING*

BY DR. H. E. WIMPERIS, C.B., C.B.E.

LATELY DIRECTOR OF SCIENTIFIC RESEARCH, AIR MINISTRY

EVER since man inhabited the earth, he has lived not by his physical powers, which are slight, but by the exercise of his wits. Every new invention he has made has had its warlike use as well as its peaceful purpose, and each has challenged his wits to ensure that good rather than harm shall result from the new discovery. To bend the newest invention of all, the conquest of the air, to the service of mankind is now his great task. In it, success is essential lest we presently find that it is the air that has conquered mankind rather than mankind the air. Before we can regard the conquest of the air as achieved, we must control the warlike menace.

I believe that the scientific advances of the present time, and their probable development in the near future, will help us to solve, and not to aggravate, our central problem—the task Lawrence of Arabia spoke of as "the biggest thing to do in the world to-day"—to bend the newest invention of all, the conquest of the air, to the true service of mankind.

Mechanical flight was achieved when Wilbur Wright flew in December 1903 in that odd-looking machine now so proudly housed in the Science Museum at South Kensington. It certainly does look a queer machine to modern eyes. Although the engine weighed 180 lb., it gave but 12 h.p.! Of course it was natural that this, like all the other early aeroplanes, should be built with two pairs of wings. Engineers were well accustomed to carrying bending moments by a form of girder construction having an upper and a lower boom, and in the biplane form of construction the loads could be carried in this familiar way. Such early trials as were made of the monoplane type merely seemed to confirm the idea that a strong wing structure could not thus be found, and the biplane became the accepted type. Speeds in those days were low, and even long after the war of 1914–18 it was thought that the attainment of high speed would be mainly a matter of putting in more and more engine power. More and more power was accordingly put in. This led indeed to the achievement of higher speeds, but far-sighted designers saw that there was a limit to the extent of progress by this means. But, as a Spanish proverb has it: "When one door shuts another opens". The new door in this case proved to be the streamlining of the external form of the craft as a whole.

That the cleaning up of the aerodynamic structure could carry performance much further than had hitherto been realized, and do so without any increase of engine power, was first clearly pointed out, little more than ten years ago, by Prof. B. M. Jones of Cambridge.

---

* From the presidential address to Section G (Engineering) of the British Association, delivered at Dundee on August 31.

Flying To-day

The consequence of these and other changes in design from the original Wright machine brought a steady growth in speed, which during the last score of years has increased by an average of well over 10 miles an hour in each year.

Speeds have grown because of the smoother shapes used in construction and through the greater engine powers provided. Can speeds continue to rise indefinitely ? We may have gone almost as far as we can in using ship-shaped forms, though we still know very little about the possibility of ensuring an increase in the extent of the laminar flow of the air over the surface of wings or body: if this could be done the resistance would drop considerably. So far as prospective increases in engine power are concerned, there is little publicly revealed in these days, but one hears of testing plants being adapted to deal with engines of no less than 3,000 h.p. apiece. But even with these increases a definite speed limit is being approached —not one imposed by the laws of any State but by the laws of Nature. As I pointed out two years ago in a presidential address to the Royal Aeronautical Society, there is good reason to believe that, although speeds of 500 m.p.h. may be attained, it is unlikely that 600 m.p h. will be much if at all exceeded, for the latter figure is some 80 per cent of the speed of sound, and when the latter is approached the drag rises to a level far ahead of any prospective engine improvements. Although nothing in the physiology of man forbids even higher speeds, as witness the high orbital speed of the earth on which we all live with some measure of tempered comfort, there is soon imposed a physiological limit if high speed is combined with rapid manœuvre. If the latter is required, then the speed must be controlled to suit the conditions. Only the future can reveal how the balance between the two will be struck.

No simple summary can be given of what has been done as regards engine development, for, great as has been the change from the fifteen pounds per h.p. of the original Wright engine to the one pound, and less, of to-day, one remembers that in this one respect the engines of the last Schneider Trophy Race were as meritorious ; where the latter were much below modern standards was in their lack of reliability when working at this power ratio. To-day's engines run without attention for hundreds of hours, a very different matter from endurance for a short race.

Even if engines of 3,000 h.p. may be said to be in sight, they are still some way from achievement. Progress depends not only on the skill of the engine designer and the metallurgist, but also on the ingenuity of the industrial chemist in producing his remarkable fuels—wonderful alike for their uniformity of quality and for their ability to resist detonation even when employed in engines of very high compression ratio.

Improvement in load-carrying capacity depends also on improvements in materials, though it is fair to designers to record the progress made in reducing the percentage which the structure forms of the total flying weight in modern aircraft. Nowadays as good a figure is shown for this in large flying-boats as in landplanes, a remarkable achievement. The flying-boat used to be thought of as slow and heavy, but to-day it holds its own, in efficiency, whether aerodynamic, structural, or economic, with any other mode of flight.

The flying-boats of to-day represent a great technical advance in quality over their predecessors of ten, or even five, years ago, but they have not yet shown any marked advance in size. The fine fleet of Empire flying-boats is made up of 20-ton units ; the new Short 'Golden Hind' class for the Atlantic weigh 33 tons apiece ; the Boeing 'Yankee Clipper' has a total weight of nearly 40 tons ; but the 'Dornier Dox' which long preceded them ran to 50 tons laden. On the other hand, there has been a great gain in speed and in carrying capacity. The Boeing boat, for example, is reported to carry 10,000 lb. of load over and above its 4,000 gallons of fuel: as this amount of fuel will weigh 30,000 lb., this makes a total load of 40,000 lb., or almost exactly half of the total flying weight, the same as for the 'Golden Hind', and a truly remarkable percentage. The improved Empire flying-boats intended for the Atlantic crossing are planned to take-off at a flying weight of about 20 tons and to take 3 tons of additional fuel after they are air borne, by supply from a flying tanker on Sir Alan Cobham's scheme. This will increase the load on the wings from 30 lb. to 35 lb. per square foot, and may be regarded as a first step towards what could be done with wings specially designed and stressed for high loading. The 'Golden Hind' class is designed for a range of 3,400 miles without refuelling, and this with full load. Its early programme may include a survey flight along the route to Latin America.

It is naturally impossible in the course of this address to discuss all the many problems in the science of aeronautics which are being investigated at the present time. They are far too numerous and the time too short. But to some of them I must refer. One of great importance and quite fascinating interest is the investigation of the change in the air flow over a wing surface from the laminar to the turbulent state. It is known that if the flow could be kept laminar, the drag would be vastly reduced, but it has yet to be discovered how to do this. A step in the right direction may lately have been made at the Langley Field Laboratories, for during Dr. Lewis's recent Wilbur Wright Lecture before the Royal Aeronautical Society mention was made of some wind tunnel tests in which a special form of aerofoil gave a drag coefficient figure of only about one-third of that usual. Further particulars will be awaited with interest. Many laboratories and experimental stations are studying this same problem, and, as not infrequently happens in such cases, success, once met with, itself creates a batch of new problems. For one thing it is clear that the presence of laminar flow can but be hindered by the use of the tractor type of airscrew now almost universal. It may be necessary to change to pusher designs, and as this will involve a marked rearward movement of the centre of gravity of the whole aircraft, all the stability factors will be gravely affected, to say nothing of the many engine problems also raised.

Other special problems relate to the possibility of having wing areas adjustable in flight by telescopic or other means, to the study of the very considerable increase in the control forces required of the pilot in large machines of high speed capacity, of the special problems raised by variable pitch airscrews, particularly in relation to the landing run, of the advantage at high air speeds of two-speed gear boxes, and of the special problems involved in pressure cabins.

The problem of the rotating wing is in a class by itself. Aircraft so fitted are quite unable to compete in speed with those with normal wings, but they easily beat the latter in take-off and landing. Many types are now in the field, the Cierva, the Hafner, the Kay and the Focke, to mention no others. The scientific problems are largely solved, as are the great mass of the mechanical ones. What is required is such a degree of user as will call for this form of aircraft to be constructed in numbers. When that happens, rotary wing aircraft will benefit in their design by that skilled attention from the production engineer which alone seems able to produce results that really look right.

The growth in recent years of the interest taken by the public in aviation, over land and over sea, is most striking. Partly, of course, it is due to the increase in the Air Arm and all that is thereby implied. But there is also a very rapidly growing use being made of the abundant facilities for air travel offered by the civil air transport services. The United States is often thought to lead the world in this respect—as it certainly does in the use of the automobile—but I believe that in proportion to the size of the population, and that is the true criterion, the total mileage flown annually is larger in Australia than it is in any other single country in the world; and there is good reason to expect that that pre-eminence is likely to continue.

THE FUTURE YEARS

Let us consider what lies ahead in the coming years in respect of speed, size and range. No doubt military craft will go as fast as they can. But since it seems that they cannot exceed 600 m.p.h. much if at all, there is little doubt that speeds between 500 and 600 m.p.h. will become usual Not so, however, for the civil air services, where quiet, comfort and cost are all-important: here there is good economic reason for speeds to settle down in the 200–300 m.p.h. range. In both these classes we seem therefore to be approaching some degree of finality.

Altitude and range are alike in that so much depends on the discovery of new materials of construction and new ways of using them. Steady progress may be expected, though probably nothing sensational unless the use of reinforced plastics be so reckoned. For civil work the advantage of long-range flying depends on the ability to fly by night, and this is advancing rapidly. Radio services are improving and the vagaries of the ionosphere are becoming better understood. High altitude flying—whether in the stratosphere or just below it—requires the sealed cabin, and it will, I fancy, chiefly be sought by those whose first care is speed and whose lesser concern is cost.

When, however, we come to think of such other factors in the future of flying as the size of the craft, and the wing loading employed, we are concerned with quite other considerations. Size depends mainly on engine power, for there is a limit to the number of power units which can be conveniently looked after. Even if we have tractor and pusher airscrews in tandem (and tractor screws may well become unpopular where the highest aerodynamic efficiency is sought), six such pairs may be the practicable limit. This would give us twelve engines, which, at 3,000 h.p apiece, makes the total power 36,000 h p. At 15 lb. carried per h.p. available, this would give a total flying weight of 540,000 lb. or some 250 tons. Such a craft would naturally be a large boat, taking two hundred passengers or more; and that is the largest flying craft that can be said to be now in sight, although I ought perhaps to mention that in a lecture to the students of the Royal Aeronautical Society, who alone perhaps might be expected to live to see it, Dr. Roxbee-Cox was bold enough to include an American forecast for a boat of 3,120 tons! But difficult as it may be to foretell accurately the future of the large flying-boat, there can be little doubt that we shall soon see such craft in active competition with their older rivals—which use the surface of the sea—for all rapid passenger transport on the important Atlantic routes.

The Air Arm

Among the world's many political preoccupations there is no more pressing or more intractable problem than that of curbing in some way the universal growth of armaments. It is true that, in so far as the product is entirely produced within the country of origin, the mere cost is of little moment. One makes armaments instead of making something else, and in the case of a people who loved above all having lots of lethal weapons, there would be nothing more to be said, though the taste might be thought odd!

It is not, however, solely a matter of finance, since normal peoples would much prefer the energy directed to armament production to be given to articles of service in civil life such as houses, pictures, sailing-boats, holiday camps and the like; and for the general body of such activity to be guided into channels which fit in with the quantity and quality of the labour available in the country. Moreover, just as a house containing a store of high explosives is not looked on as a happy abode, so there is always a fear that in highly armed international life a trigger in some remote spot may be pulled by accident, or by mischief, with irreparable harm to the whole world.

When some years ago an effort was made to come to an international understanding about air armaments, success was not attained. This was due, it is true, in some measure to the existence of strong professional interests and to the relative lack of attention to the needs of the ordinary man, but it was partly due to the inherent difficulty in the then state of the art of distinguishing between military and civil types. Even suppose, it was asked, that one could abolish all military aircraft, how would one deal with the civil types which could be so easily converted? In those days this was a germane question. But is it now? I think not, and for this reason.

The speeds of military aircraft are now in excess of 400 m.p.h. and will rise still higher. But civil aircraft rarely go faster than 250 m.p.h., and it is doubtful whether it is economically advantageous to have even so high a speed as that. This at once makes a great difference in the types. Again, the comfort and space needed for civil transport tends to produce a design of body which does not in the least resemble military requirements. In so far as the civil types in their really large sizes come more and more to take the flying-boat form, so are they the less like military types. Perhaps I should say here that I am leaving aside reconnaissance duties and troop-carrying, and thinking mainly of the aggressive type, the bomber.

Hence I submit that, as I suggested in a recent address at Chatham House, the position has been reached when, so far as technical considerations are concerned, an agreed limitation could be set on military production without the effort being nullified by the existence of civil types to which no such limitations applied. It must be remembered, however, that when a political man talks about 'parity in the air', he may not really understand what he is saying. What he probably means is equality in offensive force, for mere parity in numbers might be got by the absurd equation of putting 100 bombers plus 1,900 interceptor fighters as equal to 1,900 bombers plus 100 interceptors, because both sides add up to 2,000. It cannot worry any peace-loving country if one of its neighbours builds 1,000 or 10,000 interceptor fighters, any more than it would if that neighbour built immense numbers of anti-aircraft guns and searchlights. In fact, as a gain to the general strength of defence it would be rather comforting than otherwise.

In my view there will be no reason, once the international situation has cleared, why there should not be an agreed limitation in respect of numbers or tonnage of bombing aircraft—leaving the interceptor fighters entirely aside. It would be but cautious to agree on a limit to the speed of civil types, but as this would merely confirm what economic requirements would themselves suggest, it need be no hardship; excessively high speeds for civil types do not pay, are much more dangerous to passengers, are much more noisy to everyone, and need wasteful forms of air ports.

When this difficulty of our own age has been at last happily solved, we may be very content to leave our successors the even more threatening menace of dealing aright with the problem of atomic energy. This it is not necessary for me to describe. I will only say that, in a recent broadcast address, Prof. J. D. Cockcroft spoke of an atomic trigger action between the metal uranium and a single neutron which is reported to be capable of releasing a 100,000,000-fold increase in energy! Perhaps there are immense practical difficulties in doing this on a large scale; I earnestly hope there are! For ourselves we may well consider that in our own day we are quite sufficiently occupied with the thoughtful handling of our own special problem, how rightly to guide the future of flying.

NEWS AND VIEWS

The Universities and War

APART from the University of London, the rest of the universities of the British Isles are aiming at carrying on their work at their present posts, so far as is possible. A few departments and faculties of various universities have, we understand, made tentative arrangements to move to other quarters; but at present no steps have been taken. Dates for the beginning of the new term have been changed in certain cases. The University of Liverpool is to carry on at Liverpool, though instruction in certain faculties and departments will also be given at Harlech College on Cardigan Bay. Accommodation in certain colleges in Wales has also been acquired by that university, and will be used if necessary. So far as can be ascertained, the University of London is making the following changes: Administration—Royal Holloway College, Englefield Green, Surrey; Examinations—Courleigh, The Cleves, Reigate; University College—Aberystwyth (men), University of Sheffield (women); King's College—University of Bristol; Institute of Education—University College, Nottingham; Imperial College of Science and Technology—University of Edinburgh (Mining Department—Camborne, Cornwall); Queen Mary College—King's College, Cambridge; London School of Economics and Political Science—Peterhouse, Cambridge; School of Oriental Studies—Cambridge; Bedford College for Women—Girton College, Cambridge; Westfield College—St. Peter's Hall, Oxford; Goldsmiths' College—University College, Nottingham. The medical schools of the University are being distributed among several centres in Great Britain.

Blood-group Tests of Paternity

THE House of Lords Select Committee, to which the Bastardy (Blood Tests) Bill was referred after its second reading in February last (see NATURE, Feb. 18, p. 294), has now made its report. It will be remembered that this Bill, which was introduced in the House of Lords in December, 1938, by Lord Merthyr, sought to enable courts of summary jurisdiction to order blood-group tests to be made in bastardy cases. The chairman of the House of Lords Committee was Lord Strathcona and Mount Royal, and included among its members were Lord Dawson of Penn and the Bishop of Salisbury. The Committee gave it as its unanimous opinion that the qualities of blood underlying blood-grouping and the laws of inheritance governing the transmission of these qualities from parents to children are accepted by such a consensus of scientific opinion as to render it desirable in the interests of justice for this knowledge to be applicable to affiliation cases. After certain amendments, it recommended that the Bill be passed into law. It was stressed by the Committee that although the tests can exclude paternity in about one case out of three only, nevertheless the tests might prevent injustice. The Committee was also satisfied that the risk of error in making blood-tests has been reduced to negligible proportions; and it noted that the public is becoming ready to accept the positive verdict of science when its evidence declares against the implication of paternity to a given individual. It is indeed remarkable—and the Committee commented on the fact—how great was the preponderance of opinion among medical and legal witnesses in favour of the use of blood-tests as evidence in affiliation cases; while, of such criticisms as were offered, none disputed the validity of blood-tests as evidence.

Blood Groups and Paternity

A FURTHER refinement in the use of blood groups as a test of paternity was indicated by Dr. V. Friedenreich of Copenhagen at the seventh International Congress of Genetics which was held in Edinburgh immediately before the outbreak of war. Dr. Friedenreich, as reported in the *Lancet* of September 16, described the division of the A group into three varieties; A_1 is dominant to A_2 and A_3, and A_2 to A_3; A_3 is very rare. The distinction between A_1 and A_2 is already employed medico-legally on the Continent, thereby increasing the proportion of cases in which false accusations of paternity can be disproved. Reference to the important work of Dahr indicated a still further possibility of discrimination in that persons of constitution AA may soon be distinguished from those of constitution AO, a point of very considerable evidential value in the legal sense. From the anthropological point of view, the occurrence and distribution of groups A and B in both anthropoid apes and man constitutes a problem—so much so, indeed, that Dr. G. Montandon, of Paris, goes so far as to deny on this ground that it has any evidential value whatsoever as a criterion of race in man. Prof. Ruggles Gates, however, in a communication to the Congress at Edinburgh, argued that while gene A probably arose in the common ancestors of anthropoid apes and man, gene B in all probability arose much later by parallel mutation in both stocks.

Prehistoric Indian Village, New Mexico

AN expedition of the American Museum of Natural History of New York, under the leadership of Dr. Paul S. Martin, has been engaged in the examination and excavation of a number of Indian village sites in the mountainous region of western New Mexico. The villages are situated just off the route followed by the Spanish conquistador Coronado in his unsuccessful search for the legendary wealth of the "Seven Cities of Cibola". According to a preliminary report from Dr. Martin, of which certain particulars have been issued through Science Service of Washington, D.C., there was little surface indication of the existence of any of the sites; and it was only the occurrence of scraps of Indian pottery, no larger than a thumb-nail, which directed the attention of the members of the expedition to one site which has been excavated. Even local pottery-hunters had failed to detect the existence of the villages. On this site the walls and floor of a large subterranean pit-house, presumably used by the inhabitants for ceremonial celebrations, has been uncovered. It measures 33 ft. in diameter, and is the largest of its kind hitherto excavated in this area. The objective of the expedition is the identification of sites belonging to the little-known Mogollon culture, one of the three cultural divisions into which American archæologists now classify the prehistoric cultures of the south-west, preceding and leading up to the great development of the Pueblos. Dr. Martin reports that he has found important evidence relating to the age and development of the Mogollon culture. He estimates that the site excavated was abandoned seven hundred years before Coronado's expedition of about the middle of the sixteenth century.

Archæological Reconnaissance in Roman Scotland

ALTHOUGH by this time the value of the aeroplane in archæological investigation stands in little need of further testimony, a record of recent discovery in Roman Scotland not only renews, as it were, the wonder at its achievement, but also affords striking evidence of how its use, and intensive examination of a terrain from the ground itself, combine with and supplement one another. The occasion of the demonstration was a survey from the air made in June last by Mr. O. G. S. Crawford, editor of *Antiquity* and archæological officer of the Ordnance Survey, to supplement previous work in preparation for archæological maps of Roman Scotland to be published by his department. The survey from the air was amply justified. It solved a number of knotty problems standing over from previous investigation, even after intensive field work, and in addition it added fresh data in the form of previously unrecorded native and Roman forts and fortlets, as well as a number of other discoveries of interest along the lines of the Roman roads in Annandale. Flying farther afield to the north, Mr. Crawford identified a Roman fort farther north of the Antonine Wall than any previously recorded, and on the return the modern method of reconnaissance was able to authenticate a site that has long been on record. Not only was it possible to make out the remains of rampart and road, both by observation and photograph, but also it can now be stated with complete certainty that it is a Roman fort, and further that a Roman road ran north-east from the gate in the rampart on that side of the fort—a fact of which certain implications for Roman dispositions in Scotland are made the subject of preliminary discussion in *Antiquity* of September by Mr. Crawford in his account of the reconnaissance.

Medicine in Ancient Ireland

IN a recent address before the Irish Free State Medical Union (*J. Irish Free State Med. Union*, 5, 22; 1939) Dr. T. P. C. Kirkpatrick stated that, like many other peoples, the Irish had a traditional god of healing, named Dianecht, who fitted the silver hand to King Nuada about the year 1272 B.C. According to the genealogies of MacFirbis, there were other physicians such as Eaba, the female physician, the second doctor who came to Erinn, and Fingen, who was physician to Conchobha MacNessa, whose hand he sutured with golden threads to match his hair. There is also some evidence of medical education in the country, as Josina, the ninth King of Scotland, came to Ireland about the second century B.C. to study medicine. There were, moreover, numerous schools in ancient Ireland, such as those at Clonard, Armagh, Clanmacnoise, Monasterboice and Portuma, in all of which medicine was probably taught. The Brehon or Ancient Laws of Ireland, which according to tradition were written down about the time of St. Patrick but had been in force for some time previously, show that the status of the leech or physician was well defined. In an ancient law tract an elaborate account is given of "Othrus" or "Sick Maintenance", which enacted that a person who had received physical injury from another should be given by his assailant not only the ordinary legal fine but also certain medical expenses. The position of the leech corresponded with that of the smiths, builders, gold-workers and Brehons, who were all high up in the social scale. The fees were fixed and depended on the social position of the patient and the nature of the disease. In addition to medical schools there were also hospitals, such as the "House of Sorrow" attached to the Red Branch at Emania where sick and wounded persons were treated, and the "Forus Tuatha" or territory house which is mentioned in the law tracts as a sort of hospital. Dr. Kirkpatrick concludes that medicine in ancient Ireland was probably as well developed as in any other contemporary country in western Europe.

Alcoholism and Mental Disease

IN his inaugural thesis (*Thèse de Paris*, No. 489; 1939), which is based on his experience at the Lesuellec Psychiatric Hospital, Dr. André Le Gall deals with the subject of alcoholism and mental disease in the Morbihan Department of Brittany. He points out that during the period 1910–37, since when the number admitted to the hospital each year has remained almost stationary, the admissions increased from 149 to 335, while the percentage of alcoholic patients rose from 7·52 in 1920 to 44·77 in 1937. The consequence has been that the total number of patients under treatment at the hospital rose from 778 in 1920 to 1,474 in 1938. There has also been a considerable increase in alcoholism among women, as is shown by the fact that while in 1911 they formed only 18·90 per cent of the total number of alcoholics, in 1937 this figure rose to 43·33 per cent. For several years the average age of the alcoholic patients has shown a tendency to fall, young persons of 20–30 being more numerous than formerly. Alcoholism was found to be as frequent among the married as among celibates, but was more liable to affect the rural than the urban population. In 1936, for example, only 15·73 per cent of the alcoholic admissions were manual labourers, as compared with farm labourers who formed 47·25 per cent of these admissions. The measures suggested by Dr. Le Gall for the control of alcoholism in Morbihan include suppression of the privileges allowed to home distillers, limitation of the number of public houses, the creation of dispensaries of mental hygiene, special homes for inebriates, especially for relapsing cases, the promotion of sport, and the encouragement of propaganda in favour of non-fermented apple juice, which has yielded excellent results in some countries, especially Switzerland.

Earthquake near the New Hebrides

THE United States Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the epicentre of the earthquake of August 12 to be provisionally latitude 13° S., longitude 169° E. The instrumental reports from Manila, Sitka, Weston, St. Louis, Fordham, Pasadena, Honolulu and Philadelphia also suggest that the depth of focus from which the shock originated was of the order of 150 km., thus making a deep focus earthquake. The epicentre is to the north of the New Hebrides and north-west of Fiji, being submarine in character. No damage has been reported, either directly due to the shock or to any abnormal sea waves. The region concerned is particularly liable to earthquakes and it is also noticeable that the frequency of earthquakes having deep focus is greater than normal in the whole of the region extending from Japan to the south of Fiji and including the area in question. A new Milne-Shaw seismograph and high-precision clock with seconds regulator have recently been sent on loan to Fiji by the British Association Seismological Committee at the suggestion of the Seismological Committee of the Australian and New Zealand Association for the Advancement of Science to replace the old Milne instrument there. This new seismograph will be particularly valuable for obtaining data for the study of deep focus earthquakes similar to the one mentioned above.

Mathematical Reviews

THE American Mathematical Society has founded a new international mathematical abstracting journal to be known as *Mathematical Reviews*. The first number is to appear late in 1939 or early in 1940; the material to be reviewed begins with the latter half of 1939. It is proposed to review all fields of pure mathematics and also those of applied mathematics and mathematical physics which are of pronounced interest to mathematicians. The new journal, which will be issued approximately once a month, will contain several thousand reviews annually and will run to approximately eight hundred large double-column pages. Prof. J. D. Tamarkin and Prof. Otto Neugebauer will be the first editors. The Carnegie Corporation has appropriated 60,000 dollars as a reserve for the new journal. The Rockefeller Foundation has made a gift of 12,000 dollars to cover some of the initial costs. Brown University is housing the project and aiding in the editorial work. The American Mathematical Society and the Mathematical Association of America are each beginning with a subsidy of 1,000 dollars for the first year. Annual subsidies are being sought from other organizations, and plans for the permanent financing of the project are being considered. On account of the generous subventions, the subscription price will be set drastically below actual cost.

PARTLY with the view of aiding indirectly in the support of this journal, the Rockefeller Foundation has made a handsome gift to Brown University for an experiment in the dissemination of mathematical publications through the distribution of microfilm. This money is to be used to augment the mathematical library at that University, a collection which is already internationally known as outstanding. Out-of-print journals will be put on film and made available to mathematicians; rare books of general use will be filmed; on request from a subscriber to the new journal, any article reviewed will be sent on film or as film-print. This service will be extended to all parts of the world at a price not exceeding cost. It should be of greatest value to mathematicians in the smaller universities and colleges, and should be a factor in encouraging young men to continue with their investigations.

Matter and Radiation

No. 704 of Hermann's "Actualités" series is by Prof. Louis de Broglie, editor of the volumes on theoretical physics, and is entitled "Le Principe de Correspondance et les Interactions entre la Matière et le Rayonnement". It extends to 170 pages (Paris: Hermann et Cie. 50 francs). The first 48 pages give an account of Maxwell's equations and their extension by Lorentz to cover electrons; the electromagnetic theory of dispersion; the theory of quanta; the correspondence principle introduced by Bohr in 1916; and Heisenberg's representation of the atom by a matrix of quantities all of which are directly observable. Then the principle of wave mechanics is introduced according to which the movement of material corpuscles is based on a certain equation of waves developed from the Hamiltonian function of classical mechanics. It is then shown that wave mechanics includes the correspondence principle and leads to a theory of the interaction of radiation and matter which, though not strictly logical, may be regarded as a first approximation. Later sections deal with the diffusion of light energy by matter, first without change of wave-length, then with such changes as are illustrated by the Compton and the Raman effects. The volume concludes with a study of photo-electricity in which the light quantum passes completely to matter, that is, the photon is annihilated. As one would expect from the author, wave mechanics is treated with great clearness and there is no attempt to represent the theory as having resolved all difficulties; on the contrary, at each partial success its incomplete nature is commented on and the requirements of a more complete solution are specified.

Egg Storage

A DESCRIPTION is given in the *Electrical Review* of September 15 of the Chelmsford Egg Supply Co. (1934). This company utilizes a process for the preservation of eggs which, it is claimed, keeps them fresh indefinitely. It is said that, if eggs are frozen below 28° F. they crack, so that storage by freezing is impracticable. Storage in gas is better, but it takes time for the gas to percolate through the shell. The company has, however, overcome this difficulty. Every egg has a small air space at the top. This increases as the egg ages. By means of a pump the air is extracted and replaced by carbon dioxide and nitrogen under a pressure of 250 mm., this pressure being maintained all the time the eggs are in storage. The eggs are stored in large cylinders each holding 234,000 eggs and are kept at a temperature of 30° F. Each refrigerating unit is driven by a 6 h.p. motor, and in addition, two extra motors are employed, 5 h.p. and 2·75 h.p. respectively, for circulating the water and ammonia. The gas-tight cylinders in which the eggs are stored look like large boilers. An additional chamber held at a much lower temperature is used for freezing liquid eggs, that is, those which have been accidently cracked, and are sold to local bakeries. The factory is also a national mark packing station capable of dealing with a million and a half eggs a week. The electricity taken per annum from the public supply is nearly 60,000 units. As this load is very nearly constant, and is heaviest during the summer months, the load factor is excellent and an attractive tariff is available. The seasonal difference in the price of eggs practically makes up for the cost of storage.

Extensions of Carrier Telephone Systems

IN the quarterly edition (No. 17) of *Nippon Electrical Engineering*, published in English by the Institute of Electrical Communication Engineers of Japan, there is an important paper on carrier telephone systems which make use of lighting and power distribution lines. It is written by N. Shinohara, Y. Hirano and M. Yoshioka, and contains many useful experimental and theoretical results. They point out that the economies effected by using existing power and lighting circuits as part of the carrier system make it possible to extend communication to out-of-the-way districts, as, for example, farming districts, fishing villages, lighthouses, etc. This will make possible the rapid cultural development of these places. They consider first of all the use of high-tension distribution lines as part of the carrier frequency transmission circuit. In the past this has been done by two systems; the first is called the metallic circuit system and the second the ground return circuit system. Although the first system excels the latter so far as low attenuation and noise are concerned, the second is the system which is more commonly employed owing to its greater economy and trustworthiness. The authors state that in utilizing the high-tension distribution line it is best to employ the ground return circuit system. The most commonly employed types of high-tension systems are the single-phase two-wire type and the three-phase three-wire type. The height of the wires above the ground is not uniform, but, where the line is even, the average height is about seven metres. By considering a single copper wire 5 mm. in diameter at a height of 7 metres above the ground and at a temperature of 20° C. and a frequency of 50 kc., they compute that the speed of the carrier waves is nearly equal to the speed of light and that the attenuation constant is very small. They conclude by describing a method of designing a circuit by a new telephone system which they state will be the most suitable for a rural district. They show how much more economical the new system would be than the one at present in use.

Oceanographical Results from Central America

IN July and August 1938, the President of the United States, the Honorable Franklin D. Roosevelt, undertook an inspection cruise and fishing expedition from San Diego, California, to Pensacola, Florida, by way of the Panama Canal, aboard the U.S.S. *Houston*. Between July 16 and August 9 some 5,888 miles were covered and fourteen different collecting stops were made, distributed among the possessions of five different nations: Mexico (Lower California and Socorro Island), France (Clipperton Island), Ecuador (the Galapagos Islands), Costa Rica (Cocos Island), and Colombia (Old Providence Island in the Caribbean). Dr. Waldo L. Schmitt of the United States National Museum accompanied the expedition as a naturalist. The results are published in a series of papers of which four are before us: "Decapod and Other Crustacea" (with Introduction and Data) (Smithsonian Miscellaneous Collections, 98, No. 6, Pub. 3531) by Waldo L. Schmitt; "Mollusca" (Pub. 3535) by Paul Bartsch and Harald Alfred Rehder; "A New Holothurian of the Genus Thyone" (Pub. 3537) by Elisabeth Deichmann; and "Two New Gobioid Fishes" by Isaac Ginsburg (Pub. 3539), May–June 1939. A number of new species of Mollusca are described, and lists of species given from the various collecting grounds.

Grass Drying

A REPORT on fodder conservation with special reference to grass drying by E. J. Roberts has been published by the Agricultural Research Council (H.M. Stationery Office. 2*s*.). This is the third report on the subject, and embodies the results of the most recent experiments carried out with the co-operation of agricultural organizers, colleges and experimental farms in Great Britain. A detailed account of grass-drying machinery and equipment is given, and comparison made with the various processes of artificial drying in other countries. There seems to be little doubt that the conservation of young grass is sound in principle, as it is then at its maximum nutritive value, and feeding trials show that it can largely replace concentrates. The question of the profitableness of grass-drying, however, cannot be answered so simply, as it depends both on the quality of the product and also on other matters such as the market value of the concentrates which it is to substitute, and whether the grass would have been utilized in some other manner or wasted through occurring at a time of surplus growth. The indirect advantages of the process, such as improvement of the sward, control of thistle, etc., must not be overlooked, nor the fact that the lower grades of dried grass are of higher value than the best hay. Profit-making, however, in this as in many farming enterprises, depends to a very large extent on the skill of the individual.

Agricultural Libraries

THE International Institute of Agriculture in Rome has just published a useful book of reference entitled "International Directory of Agricultural Libraries" (25 lira). The information consists of a list of all general agricultural libraries of more than two thousand volumes, libraries specialized in particular subjects, agricultural collections in general libraries, and centres of agricultural documentation. So far as possible, the history and size of the library and the subjects represented therein, the cataloguing and classification systems employed and regulations for the use of the library are stated. Relations with other libraries (exchange of publications, etc.), a bibliography of writings on the library and any publications edited by it are also mentioned. 1,200 libraries arranged according to country are described, and the text is written in both English and French.

Theodor Langhans (1839-1915)

THEODOR LANGHANS, an eminent German pathologist, who with the physician Sahli and the surgeon Kocher formed a triumvirate which made the Berne medical school famous, was born at Usingen, Nassau, on September 28, 1839. He received his medical education at Heidelberg; Göttingen, where he was a pupil of the celebrated anatomist Henle; Berlin, where he studied under Virchow, Trauber and Frerichs; and Würzburg, where he qualified in 1864 with a thesis on the structure of tendons and served as assistant to von Recklinghausen until 1867. He then went to Marburg, where he collaborated with Lieberkühn and Wagner in anatomical research. In 1868 he described the giant cells in tubercle to which his name has been given, and it was during his stay in Marburg that he carried out some important investigations on the absorption of extravasations and the formation of pigment. In 1872 he was appointed professor of morbid anatomy at Giessen, but in the same year succeeded Klebs in the corresponding chair at Berne, where he did valuable work on the morbid histology of the female breast, the histology of the placenta, the distribution of glycogen in normal and diseased organs, and described the cellular layer of the chorionic epithelium to which his name has been given. He also collaborated with Kocher in a study of diseases of the testicle. His later years were mainly devoted to researches on the morbid anatomy of goitre and cretinism. He retired from his chair two years before death, which took place on October 22, 1915.

Announcements

WE have been asked to state that the Geological Society of London is carrying on as usual at Burlington House. An announcement relating to meetings will be made in due course.

THE annual exhibition of the Royal Photographic Society is being held at the Society's House, 16 Prince's Gate, South Kensington. The exhibition is open from 10 a.m. until 5 p.m. daily (Sundays excepted) until October 7.

MR. JOHN RYMILL, the arctic and antarctic explorer, has been awarded the David Livingstone Centenary Gold Medal of the American Geographical Society in recognition of his leadership of the Graham Land Expedition. Mr. Rymill, who is an Australian, was a member of the British Arctic Air Route Expedition to Greenland in 1930-31, and took over the leadership when Mr. H. G. Watkins was lost. He led the Graham Land Expedition to the Antarctic in 1934.

THE Council of the Institution of Naval Architects has awarded the Martell scholarship in naval architecture (1939) to Mr. Norman W. Honey, of H.M. Dockyard, Sheerness; the scholarship is of the value of £130 per annum, and will be held at the Royal Naval College, Greenwich. The Earl of Durham Prize has been awarded to Mr. Peter E. Bish, of H.M. Dockyard, Devonport.

WE have received from the British Drug Houses, Ltd. (Graham Street, London, W.1.) the new catalogue of B.D.H. laboratory chemicals and testing outfits, which comprises nearly six thousand separate items and is provided with a general index. Section I has been enlarged by more than five hundred new items, mostly organic chemicals, and Section 2 contains an increased number of reagents and solutions for analytical and clinical purposes, and there is a new section of culture media. The products listed are normally held in stock for immediate delivery.

DR. ALBERT B. SABIN of the Rockefeller Institute of Medical Research has received the Theobald Smith award of 1,000 dollars from the American Association for the Advancement of Science in recognition of his rapid method of typing in pneumonia and for a quick bedside test of a patient's probable resistance to the disease.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 555.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Deuteron Bombardment of Silver

We have bombarded pure silver with a few microampere-hours of 9 Mv. deuterons from the Cavendish cyclotron and have used a Geiger counter for investigating the radioactive radiations. The activities observed are listed below in order of prominence.

(1) A negative electron activity of 2·4 min. is found by analysis of the composite decay curve given by irradiated silver foil, the corresponding intensity for a control sample measuring only the background neutron effect being negligibly small. This activity is to be ascribed to ^{108}Ag formed by the reaction: ^{107}Ag (d,p) ^{108}Ag.

(2) Chemical separation into silver and cadmium fractions has been performed, and the latter portion has been found to contain a 6·8 hour body emitting a soft negative electron radiation (absorption limit 15 mgm. per sq. cm. of aluminium), X-rays and a very weak γ-radiation. A body with corresponding properties has been found as a product of proton capture in silver[1], and arguments have been adduced suggesting that the activity is due either to a metastable excited state of one of the isotopes, ^{108}Cd or ^{110}Cd, electrons and cadmium X-rays resulting from an efficient internal conversion of the de-excitation γ-rays, or to K-electron capture in an unstable isotope ^{107}Cd or ^{109}Cd, giving rise to silver X-rays together with photo-electrons. Favouring the validity of the former interpretation in our case are the apparent entire absence of the positron emission which would probably accompany K-capture, and also a significantly closer correspondence of the X-ray absorption coefficient in aluminium to the value for cadmium K-radiation than to that for the silver line. The appropriate reaction is: ^{107}Ag (d,n) ^{108*}Cd, or ^{109}Ag (d,n) ^{110*}Cd.

(3) The silver fraction contains a 26-min. body emitting positrons with an absorption limit corresponding to 1·8 Mv. This body thus has properties similar to those attributed to ^{106}Ag [2]; we are, however, unable to find any trace of the 8-day period belonging to the other isomer of ^{106}Ag, and, in any event, the mechanism of the formation is obscure. A control sample given the same chemical treatment as the positive sample shows the background neutron effect to be negligible.

(4) The silver portion gives also a negative electron activity which decays with a half-life of at least several weeks.

(5) Short-lived activity in the silver foil has been sought by beginning measurements within a quarter-minute of a short bombardment, but no half-life less than the 2·4 min. can be detected.

A comprehensive account of this and cognate work will be published elsewhere.

R. S. Krishnan.
D. H. T. Gant.

Cavendish Laboratory,
Cambridge.

Through the kindness of Messrs. Krishnan and Gant, I have been able to examine the radiations from a silver foil of 20 mgm./cm.^{2} bombarded with 9 Mv. deuterons, using the method of critical absorption previously adopted in the case of the fission products of uranium[1]. For the quantum radiations from the 6·8-hour body, a palladium foil of 24 mgm./cm.^{2} was considerably more transparent than a foil of molybdenum of only 14 mgm./cm.^{2}. This is in agreement with the findings reported above, although it does not allow a decision to be made as to whether the K-radiations of silver or cadmium are involved (it is hoped, later, to use an absorber containing ruthenium in order to examine this point more closely).

Concerning the long-period activity (4, above), the method of critical absorption likewise indicates an intense quantum radiation much more strongly absorbed by molybdenum than by palladium, and a harder γ-radiation is also present. The negative electrons of the long-period activity have been examined in a special low-absorption counter arrangement, and an absorption limit of about 12 mgm./cm.^{2} has been found for them.

It will obviously be interesting to examine all these radiations in more detail to see if any reason can be found why they are so closely similar to those emitted by the 6·8-hour cadmium isotope.

Fission of Thorium by Neutrons

Since March 1938, we have been engaged in the study of artificial radioactivity induced in thorium by fast neutrons. We have already reported[1] the production of uranium Y, which was obtained in the course of this investigation.

At that time we had examined the barium and lanthanum fractions from activated thorium and obtained nearly all the periods which Meitner, Strassmann and Hahn[2] found in their study of the artificial radioactivity of thorium, and which Hahn and Strassmann[3] and other authors later identified with those for fission products of uranium and thorium, although our agreements were not exact in some cases and some other periods were obtained in our experiments.

We did not, however, follow closely these lines of investigation, since our attention was directed to a radioactive substance, which was precipitated with bismuth and lead as carriers from hydrochloric acid solution by hydrogen sulphide. We spent much time on the chemical identification of this substance. Its chemical properties were not easy to ascertain, but it was still more difficult to understand the nuclear reactions concerned. Chemical properties suggested that either 'transuranic' or elements of lower atomic number than bismuth were involved, but both these alternatives were difficult to accept at that time. Then, however, came Hahn and Strassmann's discovery of fission processes, and the problem became easier, at least in principle.

From this point of view we have been working on the chemical identification of elements for several months, but have not come yet to final conclusions. In the meantime, results on similar work were published by Bretscher and Cook[4] and by Meitner[5], but exact identification of elements was not given. Although our experiments are still in a very preliminary stage, we should like to give here the results so far obtained, since we are obliged to interrupt our work for some time.

Thorium nitrate, carefully freed from mesothorium as well as from other disintegration products except radiothorium, was exposed to fast neutrons which were produced by bombarding lithium with 3 Mv. deuterons of several microamperes from our cyclotron. The exposure ranged from one to five hours, after which the sample was subjected to chemical separations. Examination of radioactivity showed the production of the following active substances: Bi, Hg, Sb, Sn and Ag. Besides these elements, the following fractions were found to be radioactive: alkali fraction, halogen fraction, Mo-fraction, Se + Au-fraction, Cu + Cd-fraction. Identification of elements in these fractions requires further investigation.

We tested for radioactive lead and arsenic and proved their definite absence. Our chemical separations, however, took at least two or three hours and all radioactivities of short periods must have escaped our detection.

We tried similar experiments also with uranium, and so far have obtained the following radioactive precipitates: Bi, Hg, Ag, Sb + Sn, and Cu + Cd-fraction.

More thorough identification of radioactive elements both from thorium and uranium, and determination of their periods will be made in the future. Chemical procedures and details of the experiments will be given elsewhere.

We should like to acknowledge the assistance given by Messrs. N. Saito and N. Matuura in connexion with the chemical separations.

The Meson and Cosmology

THE mean life τ_0 ($\tau_0 \sim 2 \cdot 5 \times 10^{-6}$ sec.) of a meson at rest gives us a new fundamental constant of the dimension of time which lies intermediate between the 'atomic constant' τ_e (say, $\tau_e = \frac{R_0}{c} \sim 5 \cdot 5 \times 10^{-26}$ sec.) and the 'cosmological constant' t_0 ($t_0 \sim 2 \times 10^9$ years). R_0 denotes the 'classical radius' of the meson, $R_0 = \frac{e^2}{\mu c^2}$, where the symbols have their usual meaning. We shall take $\mu = 170\, m$, where m is the mass of an electron. We can construct from these basic time units (τ_e, τ_0, t_0) three dimensionless 'large numbers',

$$\frac{t_0}{\tau_e} \sim 1 \cdot 1 \times 10^{42},\ \frac{t_0}{\tau_0} \sim 2 \cdot 5 \times 10^{22},\ \frac{\tau_0}{\tau_e} \sim 4 \cdot 6 \times 10^{19},$$

and if, following Dirac and others, we make the hypothesis that 'large numbers' are interrelated, we have

$$\frac{t_0}{\tau_0} = \frac{\tau_0}{\tau_e} = \left(\frac{t_0}{\tau_e}\right)^{1/2}, \text{ or } \tau_0 = (\tau_e \,.\, t_0)^{1/2}. \qquad (1)$$

In comparing such large numbers any differences by factors of about 10^2 are to be ignored, as these could be easily taken account of by introducing the dimensionless numbers such as the fine-structure constant $\hbar c/e^2$, μ/m and H/m, H being the mass of a proton. Further, on this hypothesis we can connect the above large numbers with the (familiar) large number $e^2/G\mu^2 \sim 1 \cdot 4 \times 10^{38}$ formed from the gravitational constant G and the atomic constants e, μ. We have:

$$\frac{t_0}{\tau_e} = \frac{e^2}{G\mu^2}, \qquad (2)$$

$$\frac{\tau_0}{\tau_e} = \left(\frac{e^2}{G\mu^2}\right)^{1/2}, \qquad (3a)$$

$$\frac{t_0}{\tau_e} = \left(\frac{e^2}{G\mu^2}\right)^{1/2}. \qquad (3b)$$

Equation (3*a*) in the form

$$L_0 \equiv c\tau_0 = R_0 \left(\frac{e^2}{G\mu^2}\right)^{1/2} \qquad (4)$$

has already been given by Blackett[1].

It is of interest to note, as equation (1) shows, that in a system of measurement in which the atomic units remain constant the mean life of the meson is proportional to the square root of the epoch t_0, and as the mean life of the meson is intimately connected with β-decay, the mean life of a radioactive substance (β-activity) would vary as $t_0^{1/2}$.

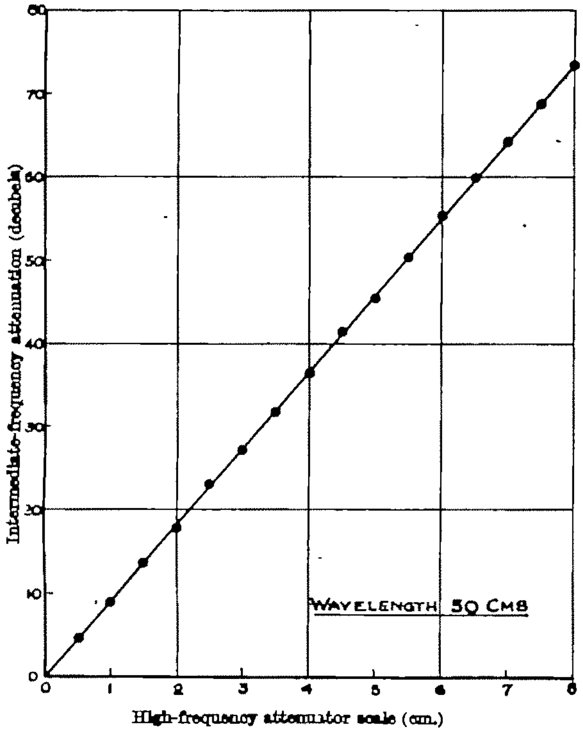
[1] NATURE, 144, 30 (1939). This has suggested the present communication. It may be noted that if in (4) μ be replaced by the electron mass, L_0 becomes the maximum radius possible for a body composed of *degenerate* matter.

The Diode as a Frequency-Changer for Measurements at Ultra-High Frequencies

THE increasing use of ultra-short wave radio communication has created a need for the measurement of oscillating electric currents, potential differences, and field strengths, at very high frequencies, up to at least 300 megacycles per second. The difficulty of measuring these quantities can be greatly reduced by converting the original frequency to a much lower 'intermediate' frequency by the well-known heterodyne process, provided that the law is known which connects the amplitudes of oscillation at the two frequencies. Theory suggests that the diode frequency-changing circuit as described, for example, by Strutt[1], possesses a linear conversion law if it is used with a heterodyning oscillation of sufficiently large amplitude. The linearity of this law has now been demonstrated by experiments carried out in the Radio Department of the National Physical Laboratory at frequencies between 4 and 600 megacycles per second for amplitudes between about 10 and 30,000 microvolts.

A variable high-frequency attenuator was constructed on the principle of the 'piston' attenuators described by Harnett and Case[2] and by George[3]. It depends on the space rate of decay of an oscillating electromagnetic field inside a conducting tube. Maxwell's theory, as developed by Rayleigh[4] and others, indicates that under the conditions of these experiments the amplitude decreases exponentially with distance along the tube, with a decay constant sensibly independent of frequency. This attenuator was used in conjunction with a frequency-changer containing a commercial diode of ultra-short wave type, together with an intermediate-frequency amplifier (1·2 mc./s.) fitted with an attenuator and an output measuring instrument[5]. The intermediate-frequency attenuator was calibrated against a standard capacitance voltage-divider constructed in the laboratory. A high-frequency signal was applied to this system and the attenuations at the high frequency and at the intermediate frequency were adjusted simultaneously in opposite senses so that a constant reading was obtained on the output instrument. Measurements were made using oscillations of various frequencies and amplitudes within the limits mentioned above. The results were expressed graphically for each frequency by plotting scale readings of the high-frequency attenuator in centimetres of tube length against the corresponding scale readings of the intermediate-frequency attenuator in decibels. The graph, which is reproduced, was obtained at 600 megacycles per second and is typical.



The points lie closely about a straight line in each case, and the slope is independent of frequency. This would occur in the improbable circumstance that any departure from exponential attenuation should be exactly complementary at each frequency to the deviation from linearity of the frequency-changer law, but otherwise the result establishes the calibration of the high-frequency attenuator and its independence of frequency, and the linearity of the relationship between the amplitudes of the high-frequency and intermediate-frequency oscillations.

It is possible, as a result of these experiments, to compare with confidence the amplitudes of high-frequency oscillations by making observations at intermediate frequency after frequency-conversion in the manner previously described.

The above work was carried out as part of the programme of the Radio Research Board, and this letter is published by permission of the Department of Scientific and Industrial Research.

Study of Diffusion Processes by Electrolysis with Micro-electrodes

THE diffusion of an electro-oxidizable or -reducible substance in solution can be studied by measuring the current obtained using suitable electrodes in an electrolysis cell under such conditions that the amount of electro-oxidizable or reducible material reaching one of the electrodes is determined only by the rate of diffusion of the material to the electrode. The concentration of the diffusing material at the electrode is maintained at a value practically equal to zero by applying a potential to the electrode such that the diffusing material is immediately oxidized or reduced upon reaching the electrode surface.

The theory of the diffusion process in the vicinity of an electrode depends upon the geometrical arrangement of the electrode and solution in contact with it. Two extreme geometric cases are represented by a flat electrode, to which diffusion can occur from only one direction (linear diffusion), and a spherical electrode, to which diffusion can occur from all directions (spherically symmetrical diffusion).

In the case of linear diffusion it can be derived[1,2] that

$$i = -A\sqrt{\frac{D}{\pi t}}\, nFC, \qquad (1)$$

in which i is the current at the time t, A is the area of the electrode, nF is the number of coulombs per mole of reacting substance, C is the concentration, and D the diffusion coefficient of the diffusing material. For spherical diffusion, the current-time equation is[2]

$$i = -4\pi RnFDC - A\sqrt{\frac{D}{\pi t}}\, nFC, \qquad (2)$$

in which R is the radius of the spherical electrode.

In testing both equations, we have studied current-time curves of different substances at potentials

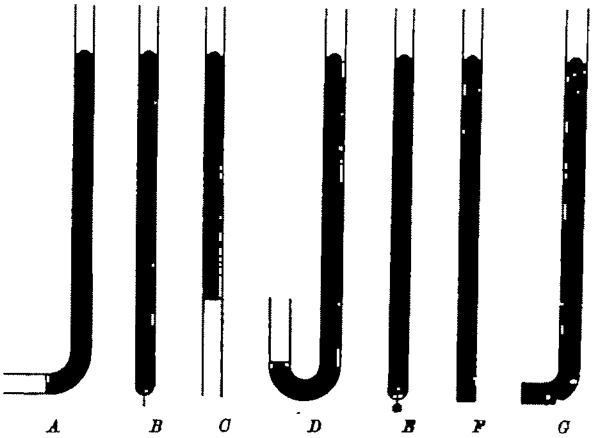

Fig. 1.

VARIOUS SHAPES OF PLATINUM ELECTRODES.

corresponding to the middle of the so-called diffusion current regions. Various electrodes of shapes shown in Fig. 1 were used. Current-time curves obtained in the electrolysis of 0·001 *M* potassium ferrocyanide in 0·1 *N* potassium chloride at 25° C. ± 0·02° are given in Fig. 2. A large 0·1 *N* silver - silver chloride served as a reference electrode. In all these experiments the potential of the platinum electrodes was 0·7 volt as referred to the silver - silver chloride electrode.

From the results presented in Fig. 2 and subsequent experiments to be reported elsewhere in detail, the following statements can be made:

(1) Theoretical current-time curves in the case of linear diffusion of potassium ferrocyanide were obtained only when using electrode *C*. In the cases of the electro-oxidation of ferrocyanide ions and of electro-reduction of silver ions at electrode *C*, where the linear diffusion was such as to produce a density gradient in the downward direction, the quantity $i\sqrt{t}$ (see equation 1) was found to be constant to ± 0·5 per cent over a period of twenty minutes. When the density gradient was in the upward direction (electrode *D*) abnormally large currents were obtained which did not give a smooth current-time curve. In the latter case, convection currents due to slight density gradients cause a greater supply of diffusing material to reach the electrode than by diffusion alone. This is the reason that in the electro-reduction of potassium ferricyanide in 0·1 *N* potassium chloride in air-free solution, theoretical current-time curves were obtained with electrode *D* but not with electrode *C*.

(2) Theoretical conditions were never attained with spherically symmetrical diffusion, due to localized convection currents as a result of density gradients in aqueous solution.

Solar Variation and the Weather

IN NATURE of April 29, p. 705, Dr. C. G. Abbot refers to the probability of weather periodicities in 274 months and factors of that interval. In this connexion it may be of interest to point out that there seems to be a periodic variation in the height of the barometer in Great Britain with a mean interval of 27·31 days.

Out of several stations examined, Greenwich had the longest series of records, and an analysis of these back to 1847, using the method of dropped days and a mean interval of 27·31 days, gave a peak averaging 0·03″ above the mean level for the 1,230 intervals between 1847 and 1938 inclusive. This peak is found to occur in all parts of the period examined but is most pronounced around 1890. In the solar cycle 1890–1901 it averages 0·054″ above the mean and consequently it is very noticeable.

The peak tends to be of a conical shape and covers about ten days of the graph. This departure from the sine curve appears to denote a complex origin, but a competent mathematician who examined the figures informs me that they are not inconsistent with a real force. On the other hand, the amplitude is about ten times that produced by the moon's tidal forces, and there seems to be nothing at present known that could account for it.

An examination of the probability of such a peak occurring by chance showed that it was very unlikely, but of course it cannot be a matter of certainty without further supporting evidence, which is being sought. It may, however, be said that Mr. F. E. Dixon examined the reported occurrences of aurora in Great Britain for about eighty years, and finds a tendency to periodicity in about 27·3 days[1].

Greenwich records go back long before 1847, but the barometer was not then read on Sundays and holidays; this introduces a further factor of uncertainty, and it was not considered that results obtained in these circumstances would be of sufficient value to justify the work involved.

The near approach of 2,731 days to a definite factor of 274 months makes some relation with Dr. Abbots' work a possibility, and from internal evidence, such as occurs when carrying out an extended analysis of this kind, I believe that there is some probability that further examination of the data, and other meteorological phenomena, may show that it is not another manifestation of the vagaries of chance.

Condensation of the Hexapeptide Ester of Glycine into the 96- and Higher (3×2^n) Peptide Esters

FOR a long time it has been known that heating under various degrees of the ester of glycine[1], glycylglycine[2] and diglycyl-glycine[3] results in the formation of certain condensation products with liberation of alcohol. If the hexapeptide ester of glycine would undergo the type of condensation exhibited by the dipeptide ester, then the simplest model of a 'cyclol 6' postulated by the Wrinch theory[4] could be prepared. The formation of such 'cyclo-hexapeptide' of glycine could then be considered as evidence for the hexagonal folding by hydrogen bonds of the polypeptide chains.

Experiments were carried out by heating the pure hexapeptide ester at a constant temperature (102° ± 1°) and samples were withdrawn for methoxyl estimation at certain intervals of time. It was found that, instead of cyclization, the hexapeptide ester underwent the type of condensation characteristic of the tripeptide ester in a series of subsequent bimolecular reactions yielding the 12-, 24-, 48-, 96-peptide (3×2^n peptide) ester of glycerine with a calculated methoxyl content of 4·33, 2·21, 1·12, 0·56 per cent and (0 per cent), respectively. When n was limited to 4 (OCH_3, 1·12 per cent) the average rate of the reaction, with the hour as the unit of time, was $10^4 K = 150$, calculated from the methoxyl content of the samples. At a temperature 10° higher, the rate of condensation was 3·7 times faster, corresponding to an activation energy of about 38 kcal. When the hexapeptide ester was heated at 130° ± 1° for six days, the methoxyl content (0·58 per cent) indicated the presence of the 96-peptide ester of glycine with the empirical formula of $C_{193}H_{292}O_{97}N_{96}$ and a molecular weight of 5504. From the nature of this type of condensation reaction, it follows that the reaction products necessarily represent a mixture of polypeptide esters. Such mixtures cannot be separated by chemical or simple physical methods.

In order to prove, first, that a hexapeptide ester does not combine with a tripeptide ester, and secondly, that the reaction products do not consist of mixtures of 'cyclol 6' and unchanged starting material, samples of diglycyl-glycine methyl ester were heated at 100° for different lengths of time and then analysed. The methoxyl content of the insoluble residues clearly indicated that, after two hours of heating, the tripeptide ester gave rise to almost pure dodecapeptide ester (found, OCH_3, 4·1 per cent; calc. OCH_3, 4·3 per cent) as the highest condensation product, and neither nonapeptide ester nor 'cyclol 6' was formed during the reaction.

All the polypeptide esters of glycine obtained in the present work are colourless substances of amorphous appearance, insoluble in alcohol but slightly (0·1–0·5 per cent) soluble in cold water. They all give the biuret reaction very strongly and dissolve completely in cold concentrated hydrochloric acid, but only partly in dilute alkali solution. They are strongly reminiscent of denatured proteins, and like many of the latter substances they are soluble in concentrated urea solution.

Although the inability of the hexapeptide ester of glycine to form a 'cyclol 6'-peptide by this method would seem strongly to favour the conception of unfolded polypeptide chains, yet, the important fact must not be overlooked that the tetrapeptide esters do not undergo[5] any type of condensation at all. This would indicate a fundamental difference between the shape of the molecules of the mono-, di-, tri- and 3×2^n-peptide on one hand, and that of the tetrapeptide and probably of the penta-, hepta-, etc., peptide on the other.

An extensive investigation by application of both chemical and physico-chemical methods is being started in this laboratory. A detailed account of the present work will be published elsewhere.

Acknowledgment is made to Dr. S. M. Trister, research assistant in this Department, for the numerous methoxyl estimations carried out in this investigation.

Catalase

Sumner and Dounce[1] have recently observed that on splitting with acids crystalline ox liver catalase yields a 'blue substance', which remains in the aqueous acetone mother liquor after the hæmin crystals have come out. This mother liquor contained approximately the same amount of iron as the hæmin crystals. The authors concluded from these observations that catalase has two bile pigment hæmatin groups in addition to two protohæmatin groups in a molecule of the weight 248,000, and that the blue substance, though not identical with the original prosthetic group in catalase, still contains iron and differs from biliverdin.

The blue-green pigment has been previously isolated by Stern[2] from horse liver catalase preparations and has been identified by Lemberg (cf.[3]) as biliverdin (dehydrobilirubin). We have now isolated crystalline biliverdin hydrochloride from a crystalline ox liver catalase of the catalase-factor 31,000, prepared by the method of Sumner and Dounce. To 25 c.c. of the catalase solution 50 c.c. of glacial acetic acid were added and the green-blue solution was poured into 300 c.c. of peroxide-free ether. After shaking with a few drops of saturated sodium acetate solution, the ether solution is poured off from the denatured protein which remains only slightly coloured. From the washed ether solution 5 per cent hydrochloric acid extracts iron-free biliverdin hydrochloride, which soon precipitates. Recrystallization from a mixture of methyl alcohol and aqueous hydrochloric acid yields the typical straight, fine needles of biliverdin hydrochloride. The compound was also characterized by transformation with zinc acetate and iodine into the biliviolin zinc complex, which possesses a typical absorption band at 637 mμ.

In a paper[3] probably inaccessible to the American authors, I have already brought forward spectroscopic evidence that biliverdin does not occur in catalase as such, but is liberated by acid from a bile pigment hæmatin-protein. One would, therefore, expect that the mother liquor of the hæmin crystals contains iron in addition to biliverdin. The preparation described above shows that iron and bile pigment are no longer combined after the treatment with acid, and that the 'blue substance' is biliverdin.

Sumner and Dounce based their conclusions as to the number of bile pigment hæmatin groups in the molecule on the equal division of iron between the hæmin and the blue mother liquor. It is, however, difficult to free catalase from an accompanying iron protein compound[6] and from inorganic iron. Keilin and Hartree[4] claim to have obtained a horse liver catalase preparation with a ratio total iron to hæmatin iron as low as 1·2. We have, therefore, studied whether there is a constant ratio biliverdin to hæmatin after acid splitting. Horse liver catalase was prepared by the method of Agner[5] followed by crystallization as described by Dounce and Frampton[6] and also by the method of Keilin and Hartree[4]. 0·5–3·0 c.c. of the catalase solutions were treated as described above. The biliverdin hydrochloride was determined colorimetrically with a standard of pure biliverdin hydrochloride; the hæmatin was determined spectrophotometrically as pyridine-hæmochromogen after extraction from the ether by dilute ammonia. 60–70 per cent of the total catalase hæmatin was thus recovered. With all crystalline preparations and in the great majority of less pure catalase preparations from ox and horse livers, the ratio biliverdin to hæmatin was close to 1 : 3. While the fractionated ammonium sulphate precipitation of Agner removed much of the accompanying iron protein, the biliverdin-hæmatin ratio remained quite unaltered. It seems also significant that only one preparation of horse liver with an abnormally low biliverdin content (biliverdin-hæmatin ratio 0·15) had an abnormal quotient activity constant over hæmatin iron ($k/F_{ep} = 770$, while we found normally 2,300). While these observations support the claim of Sumner and Dounce that bile pigment hæmatin is an essential part of the enzyme molecule, they indicate that catalase contains one, rather than two, groups of bile pigment hæmatin and three, rather than two, groups of protohæmatin. The hæmatin content of our purest ox liver catalase preparation was indeed 0·73 per cent (2·8 mol. hæmatin per molecule).

This conclusion is supported by a quantitative spectrophotometric study of the pyridine-hæmochromogen obtained from catalase. The band at 650 mμ[3] accompanying the protohæmochromogen bands is no longer observed after acid splitting and is, therefore, that of a bile pigment hæmochromogen similar to verdohæmochromogen. Its maximal extinction is only about a quarter of that of the first protohæmochromogen band at 557 mμ, while the maximal absorption of pyridine-verdohæmochromogen is more than half as high as that of this band. Although the identity of the bile pigment hæmatin in catalase with verdohæmatin is not yet established, it is very likely that the maximal absorption should be rather similar.

Since Keilin and Hartree[4] have shown that catalase undergoes reduction to the ferrous form during its action on H_2O_2, and since ferrous hæmatin compounds are easily oxidized by H_2O_2 to bile pigment hæmatin[7], it might be assumed that the bile pigment hæmatin arises during the action of the substrate on the enzyme. We have, however, failed to discover any evidence of an increase of the amount of biliverdin obtained by splitting, or of the absorption maximum at 650 mμ, subsequent to a prolonged action of catalase on its substrate.

The bile pigment hæmatin is, therefore, an essential part of the catalase molecule. The impossibility of splitting catalase reversibly into protein and prosthetic group is now explained by the lability of this prosthetic group to acid.

This investigation was carried out under a grant of the National Health and Medical Research Council of Australia.

Growth of the Mandible in the Pig

GROWTH of the mandible has been a controversial problem since the days of John Hunter, notwithstanding that he, John Tomes the elder and George Humphry in turn performed crucial experiments which showed that growth took place at the posterior border of the mandible and absorption at the anterior border, thus providing room for the eruption of the developing permanent molars.

Radiographic examination of a 'runt', the small starveling pig, shows evidence of arrested growth in the skeleton. In the scapula (Fig. 1) the successive checks to growth are displayed by lines of arrested growth, along which bony deposition is well marked. The lines are best seen at the vertebral border of the scapula, particularly at the postero-inferior angle. These lines of arrested growth have been studied in detail by me[1] in the long bones of children.

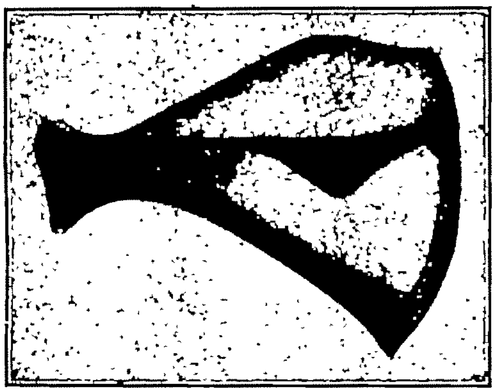

Fig. 1.

Radiograph of the left scapula of a young pig showing lines of arrested growth at the vertebral border.

In the mandible of this pig (Fig. 2) the lines of arrested growth are well marked at the posterior border, at the insertion of the temporal muscle on the coronoid process, and at the superior and posterior border of the condyle. These are the sites of alternating active growth and arrested growth.

Lines of arrested growth are absent from the anterior border of the mandible and coronoid notch. These are the sites of active absorption of bone.

The third molar, at present buried in the mandible, will erupt later by reason of the upward movement of the crown consequent upon the growth of the roots, but it will also be uncovered and laid bare by the absorption of bone at the anterior border of the mandible.

This radiographic proof of the accuracy of John Hunter's description of the growth of the mandible is in accord with the recent descriptions of madder-fed pigs by Brash[2].

The radiograph of the mandible also shows the danger, in the animal or person who is not fully grown, of making a forecast as to whether an unerupted wisdom tooth (third molar) will or will not erupt satisfactorily at a later date. Until growth in the mandible ceases at 21–25 years of age in the human, female or male, there is little justification for interference with a third molar which gives rise to no active symptoms. On the other hand, the continued refinement of the face and reduction in the size of the mandible in passing from ancient man to modern man suggests that the wisdom tooth in the future will give rise to more anomalies than in the past.

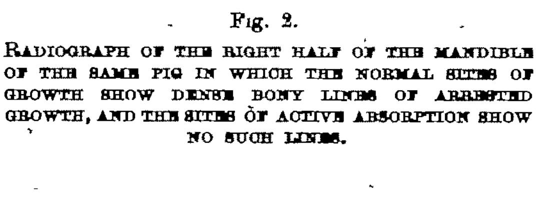

Fig. 2.

Radiograph of the right half of the mandible of the same pig in which the normal sites of growth show dense bony lines of arrested growth, and the sites of active absorption show no such lines.

Production of Intercellular Hormones by Mechanical Injury

Previous papers from this laboratory have demonstrated the production of proliferation-promoting factors (intercellular wound hormones) by cell aggregates subjected to lethal ultra-violet or X-rays[1], heteroauxin[2], and carbon dioxide[3]. These factors are evidently produced by living cells as a response to injury, since the maximum production of the hormones precedes the maximum rate of killing[3].

It has been of interest to determine whether mechanical injury would also lead to the formation of these factors. Yeast suspensions in isotonic salt solution were subjected to several types of mechanical agitation. These included various shaking devices and the rotation of bottles of the suspensions on a wheel. Very low killing of the cells was observed, and the cell-free fluids from the suspensions had slightly greater proliferation-promoting activity than the unshaken controls. The degree of increase in activity was usually small and the results were subject to considerable variation. The addition of glass beads to the suspensions in the rotating bottles gave cell-free fluids of very high activity. However, although very few intact cells were killed, many cells were completely disintegrated. It was therefore uncertain how much of the increased activity was due to intercellular hormones and how much to cellular disintegration products.

The following procedure was finally adopted. The yeast was agitated by placing it in a stoppered glass tube 1¼ in. × 3½ in. attached to the voice coil of a loud speaker, the cone of which was in the horizontal plane. The voice was actuated by a beat-frequency audio oscillator and audio amplifier. In the experiments reported, the voltage across the coil varied from 1 to 4, corresponding to a power input of 0·1–1·6 watts. A vibration frequency of 50 cycles was employed. Three and one half to 7 gm. of crumpled cake yeast were placed in the tube and vibrated for 5 hours. After the addition of 35 c.c. of isotonic sodium chloride solution the vibration was continued for another hour. Preliminary experiments showed this treatment to be more effective than vibration of a suspension for the whole period. The growth potencies of Berkefeld filtrates of the suspensions were compared with those of controls which were treated in the same way except that vibration was omitted. In later experiments increased potency was obtained by adding sand to the yeast during agitation. This did not markedly increase the amount of killing as determined by methylene blue staining, nor was fragmentation of the cells observed. About 25 per cent of the cells were killed. The experimental filtrates were one and one half to two and one half times as potent as the controls on a volume basis, and one and one half to four times as active on the basis of equal weights of solid in the filtrates.

Preliminary experiments indicate that the active materials, like those from ultra-violet injured yeast cells[4], are characterized by ultra-violet absorption at 2600 A.

Exfoliation of Vermiculite by Chemical Means

SPECIMENS of vermiculite from different localities have been examined in the laboratories of the Mineral Resources Department of the Imperial Institute in the course of an investigation into possible Empire sources of supply, and an interesting phenomenon has been observed in connexion with the expansion of the mineral, a property on which its commercial value depends. This expansion is usually brought about by heating the material, and a record of an instance in which it has been effected by chemical treatment appears to be of scientific interest.

It has been noticed that in the mechanical analysis of soils, the preliminary treatment with hydrogen peroxide causes some alteration in the appearance of weathered mica particles present in the soil. This suggested that hydrogen peroxide might have some action on vermiculite, and in order to ascertain its effect a number of small pieces of the mineral, about ¼ inch in diameter and less than 1/10 inch in thickness, were covered with the reagent (20 vol. strength) and allowed to stand. Complete exfoliation takes place after some time in the cold and can be hastened by gentle heating. A preliminary drying of the mineral at 100° C. was found to accelerate the action in one instance. The treated specimens have a concertina-like appearance, the lamellæ forming the bellows, and with one specimen alternate light and dark coloured zones were observed parallel to the direction of expansion, which is curved. The material treated with hydrogen peroxide is of a paler colour than that exfoliated by heat, and provided that it is kept moist, is also very soft, requiring only gentle rubbing or stirring, rather than grinding, to reduce it to a fine state of subdivision. The mechanical strength of the treated and still moist product is low, but after drying in a steam oven, its properties are similar to those of the heat-treated material.

The exact cause of this effect has not yet been ascertained. It has always been considered that the exfoliation of vermiculite on heating is due to the separation of individual lamellæ by the evolution of combined water, but this would not explain the similar effect obtained with hydrogen peroxide. The effect obtained may possibly be due to evolution of oxygen between the flakes of the mineral, but this does not explain the asymmetric expansion or the zones of different colour.

Various other oxidizing and reducing agents (potassium permanganate, potassium dichromate, chromic acid, sodium hypobromite, chlorine generated from permanganate and hydrochloric acid, water saturated with sulphur dioxide) have been tried, but none of them has given an expansion at all comparable with that obtained with hydrogen peroxide, although some effect was observed in certain instances after long standing. Chlorine from permanganate and hydrochloric acid, for example, causes a certain amount of exfoliation and separation of the lamellæ but not to the extent given by hydrogen peroxide.

Technique of the Painting Process in the Bagh Caves in Gwalior State

THE Bagh caves (lat. 22° 22′ N., long. 74° 48′ E.) are situated among the southern slopes of the Vindhya Hills, seventy miles from Mhow, a town on the Rajputana-Malwa section of the B.B. and C.I. Railway. The caves were at one time fully decorated with paintings. But there are remains of them[1] only in caves III and IV. The caves, which are of sandstone, have crumbled, due to the excessive weight of the superimposing band of claystone with moisture percolating through it. Consequently many of the paintings have disappeared. The paintings probably belong to the early seventh century A.D.[2], being contemporaneous with the paintings in Caves XVI and XVII at Ajanta.

The paintings of Bagh and Ajanta form a class by themselves. They belong to the golden age of Indian classical art, which inspired more than half the art of Asia. They will bear comparison with the best that Europe could produce down to the time of Michelangelo[3].

In the course of my studies[4] on Indian paintings, I recently investigated the methods and materials used by the classical artists at Bagh. The paintings are done on the sandstone wall of the veranda lining Caves IV and V. The painted stucco, consists of rough plaster of ferruginous earth or of lime. The earth plaster has a thin smooth coat of a mixture of gypsum and lime. The lime plaster has a thin coat of limewash. These thin coats support the layer of paint. The rough plasters of earth and of lime vary in thickness from 7·9 mm. to 20 mm. and from 3·4 mm. to 6·5 mm. Their average thicknesses are 17 mm. and 4·9 mm. respectively. With the earth stucco, the gypsum-lime layer and the paint layer are each 0·1 mm. thick. In the lime stucco, the limewash and the paint film are each 0·2 mm. thick. 48 per cent of the deep red plaster is composed of particles the sizes of which vary from 200 μ to 700 μ, while 16 per cent of them are less than 200 μ and 36 per cent greater than 700 μ. The corresponding figures for the light red earth plaster and the lime plaster are 40, 20, 40 per cent and 40, 60, 0 per cent respectively.

The results of analyses of the rough plasters are as follows:

	Earth plaster Deep red Per cent	 Light red Per cent	Lime plaster Per cent
Moisture	0·27	0·42	0·91
Carbon dioxide, CO_2	1·25	0·65	12·68
Combined water and organic matter	0·65	1·03	9·34
Silica, SiO_2	87·22	87·10	51·18
Iron, Fe_2O_3	6·12	3·11	2·23
Alumina, Al_2O_3	0·44	5·29	
Phosphoric acid, P_2O_5	0·12	0·10	
Titanic acid, TiO_2	0·09	0·07	
Lime, CaO	2·11	0·75	22·41
Magnesia, MgO	0·56	0·44	nil
Manganese, MnO	0·75	0·39	nil
Sulphuric anhydride, SO_3	nil	nil	0·04
Alkalis	0·44	0·62	1·21
Nitrogen	0·13	0·09	nil

The consolidation of the earth plaster is due to the plasticity of clay[5] present in it. It has also been reinforced and bound with vegetable fibres[6]. The firmness and strength of the lime plaster is due to the lime present and to the considerable quantities of long vegetable fibres originally added.

The pigments employed at Bagh are yellow and red ochres, carbon, lime and gypsum, terre verte and lapis lazuli. Animal glue has been added to the pigments to serve as the binding medium on the earth plaster, while the pigments have been employed in *lime medium* on the lime plaster.

Full details of the investigation will be published elsewhere.

Points from Foregoing Letters

R. S. Krishnan and D. H. T. Gant have bombarded silver with deuterons from a cyclotron. They find a negative electron activity of period 2·4 min. Chemical separation of the irradiated silver into silver and cadmium fractions has been carried out. The cadmium fraction contains a body of 6·8-hr. period emitting soft negative electrons, possibly due to a cadmium isotope; the silver fraction contains a body of 26-min. period emitting positrons. N. Feather has confirmed some of the previous workers' findings, using the method of critical absorption.

A group of Japanese workers report on their investigations on the fission of thorium by neutrons. They bombarded thorium nitrate with fast neutrons for periods of one to five hours and attempted the chemical identification of the radio-elements produced.

D. S. Kothari derives a set of equations connecting the mean life of the meson τ_0, the cosmological constant t_0 and the gravitational constant G.

Experiments with a diode frequency-changer are described by G. F. Gainsborough which demonstrate the linearity of the relationship between the amplitudes of the high-frequency and intermediate-frequency oscillations, thus permitting comparisons of ultra-high-frequency alternating potential differences to be made after frequency conversion. The calibration of the high-frequency attenuator used was shown to be valid at frequencies up to 600 megacycles per second.

H. A. Laitinen and I. M. Kolthoff show quantitatively the disturbing effects of convection currents on diffusion studies with micro-electrodes and indicate the conditions under which theoretical diffusion conditions can be realized in electrolysis with micro-electrodes.

Barometer readings at Greenwich for the last 92 years seem to show a periodic variation with an interval of 27·31 days. A similar tendency has been observed in the reported occurrences of aurora. W. R. Priston suggests this may have a connexion with Dr. Abbots' period of 274 months (Nature, April 29, 1939) in meteorological phenomena.

E. Pacsu finds that condensation by heat of the hexapeptide ester of glycine gives 12-, 24-, 48-, etc., peptide esters, the number of glycine molecules being expressed by the general formula of 3×2^n. The condensation at 102° proceeds through a series of successive bimolecular reactions with $10^4 K = 150$ and has an activation energy of 38 kcal. Analysis shows that neither 'cyclol 6' nor nonapeptide is formed in the reaction. The substances are reminiscent of denatured protein and give strongly the biuret reaction.

R. Lemberg, M. Norrie and J. W. Legge find that catalase contains one bile pigment hæmatin group, similar to verdohæmatin, in addition to three protohæmatin groups. By splitting with acids, biliverdin is isolated from crystalline catalase. Evidence is brought forward in support of the view that the bile pigment hæmatin is an essential part of the enzyme molecule.

That the sites of active growth and of active absorption of bone are displayed by a radiograph of the lower jaw of a young pig which had grown irregularly is submitted by H. A. Harris. The satisfactory cutting of the wisdom tooth depends largely on the degree of absorption of bone at the anterior border of the jaw.

It has been shown by J. R. Loofbourow and coworkers that proliferation-promoting factors (intercellular wound hormones) are produced by cell aggregates on subjection to ultra-violet light or X-rays, heteroauxin or carbon dioxide. Loofbourow *et al.* have now examined the effect of mechanical injury, in this respect, by subjecting yeast cells to vibration induced by the voice coil of a loud speaker. Increased growth potency of the filtrate was observed in those subjected to agitation compared with the controls.

Miss R. C. Groves states that vermiculite, a mineral used commercially for heat- and sound-insulating purposes, can be exfoliated by means other than the usual dry heat treatment, and records an instance in which the effect is produced by the action of cold hydrogen peroxide.

RESEARCH ITEMS

Excavations at Brundon, Suffolk

THE gravel pit at Brundon, near Sudbury, Suffolk, affording a rare opportunity of examining a true interglacial bed, a research committee was appointed by the British Association for the purpose of its excavation. The actual work of conducting the examination was carried out under the supervision of the committee by J. Reid Moir in 1935–37, by whom a report on the work of excavation and the archæological material has been prepared, while A. Tindell Hopwood has reported on the fossil mammals. (*Proc. Prehist. Soc.*, 5, 1; 1939). The Brundon section, the base of which lies approximately at 100 ft. O.D., is composed of Upper and Lower Glacial deposits separated by fluviatile beds. The geological, archæological and palæontological evidence points to the probability that the basal Boulder Clay at Brundon was laid down by the Upper Chalky Boulder Clay glaciation. The age of the upper glacial deposit remains uncertain; but it may be that of the Brown Boulder Clay of Hunstanton, Norfolk. At the base of the fluviatile gravel (Stratum 3) at Brundon are traces of an ancient land surface, rich in mammalian remains and non-marine Mollusca. At this level occur unabraded and unpatinated flint implements and flakes of Crayfordian types. The evidence of the fossil bones and shells also points to the deposit being of the period named, post-dating the glaciation responsible for laying down of the Upper Chalky Boulder clay, a conclusion supported by the discovery of Baker's Hole type of implements with the unabraded artefacts. The former are patinated, abraded and striated, suggesting that they had experienced glacial conditions before reaching the Brundon ancient land surface. In the fluviatile gravel implements of various ages have been found—Early Clactonian, Early and Late Acheulean, Baker's Hole and Crayfordian. The upper glacial deposits have yielded a few indeterminate flakes only. There is good reason to believe that the climate during the laying down of the fluviatile deposits was warmer than that of to-day, and that the Brundon section represents a true interglacial accumulation, resting upon and surmounted by deposits laid down during a period of extreme cold.

Ancient House Types in Arizona

INVESTIGATIONS by Dr. Frank H. H. Roberts, jun., on behalf of the Bureau of American Ethnology and the Laboratory of Anthropology, Santa Fé, on archæological sites in eastern Arizona, mainly on the ridge of mesas west of Whitewater Creek, near Allantown, in three successive seasons in 1931–33, have produced valuable information relating to one component of the prehistoric sedentary Indian culture pattern, of which that bearing on house-types is now published (Smithsonian Inst. *Bur. Amer. Ethnol.*, *Bull.*, 121, 1939). The remains belong to several stages of the Anasazi cultural pattern. There are traces of Modified Basket-maker, and large ruins represent the Great Pueblo period; but most of the digging was done in Developmental Pueblo remains, in which twenty pit structures with their accompanying granaries and surface shelters, and three unit-type ruins were examined. They clearly show the growth from small single-roomed pit-dwellings, with brush- and plaster-covered truncated pyramidal superstructures, supported by four upright posts set in the floor of the chamber, to above-ground houses with several contiguous rooms, masonry walls, and flat roofs. Correlated with this is the shift in function of the semi-subterranean domicile from secular to ceremonial purposes. This change is accompanied by comparable changes in other features, particularly in the lesser objects of the material culture, such as pottery, stone, and bone implements, which will be considered in a later report. Charred beams indicate by the dendrological method an occupation of the remains excavated extending over a period of two centuries, dated from A.D. 814–1014.

Excavations at Mas d'Azil, France

EXCAVATIONS by Marthe and Saint-Just Péquart at Mas d'Azil, on the left bank of the Arize, although not yet completed, call for an interim report on four seasons' work (*L'Anthropologie*, 49, 3–4, 1939). The stratigraphic evidence reveals three occupations by Magdalenians, separated from one another by sterile layers of soil, varying in depth respectively from 2 metres to 1 metre. The Azilian layer of occupation, however, except for certain traces which the excavators have succeeded in isolating, had virtually disappeared, and with it the neolithic stratum. In a second terrace under examination, the neolithic people had settled on a layer of clay which seals the Magdalenian, no evidence of Mesolithic occupation intervening. At its greatest thickness this neolithic layer is four metres deep, but has yielded little in the way of artefacts. The Azilian finds include three bone harpoons representing the two Azilian types. In the second Magdalenian horizon—the first provided few relics—a quantity of material in bone includes some sixty blade-bones, of which one half were unused while the other half was scored or in many instances engraved with recognizable figures of animals—reindeer, horses, etc., while in a hunting scene are rudimentary human figures. On the right bank in excavations by M. and Mme. Mandement four galleries have been opened up in the cave, of which the existence was previously unsuspected. Of these one was found to be rich in Magdalenian deposits, including some remarkable examples of Magdalenian art, now in the St. Germain Museum.

Elements in Nutrition

A SURVEY of up-to-date knowledge of elements which appear to be essential when present in traces in human and animal foods is given by W. Godden (*J. Soc. Chem. Ind.*, 58, 791; 1939). Copper in small amounts appears to be necessary in preventing anæmia in animals, the food of which nevertheless contains adequate amounts of iron; its role is not concerned with the assimilation of iron but with the mobilization of iron in the body and with the formation of hæmoglobin. Milk is very low in copper as well as in iron, but copper is present in most other foods. Manganese plays no part in hæmoglobin formation, but appears to be necessary for fœtal development. Cobalt is in some cases essential to iron metabolism, and diseases of farm animals in Australia and New Zealand have shown it to be an essential element in the cure of bush-sickness; traces of nickel may possibly supplement deficiency of cobalt. Zinc does not play any part in iron metabolism; it is present in higher percentage than copper or manganese in human and cow's milk and is a constituent of crystalline insulin. Fluorine is present in bones and the enamel of teeth, but when present in more than mere traces it affects the enamel of teeth; this may be caused by drinking waters containing more than 1·5 parts per million of fluorine. Iodine deficiency has long been recognized as a probable cause of goitre. Selenium is a harmful element, and its presence in soils of the Great Plains of the United States, from which it finds its way into herbage and cereal grains, causes diseases of animals which were formerly regarded as due to the alkali present in the waters of these regions. The paper includes a short bibliography.

Genetics of Man

ONE of the valuable contributions of Mendel was to show that the dominant individuals in an F_2 generation consisted of homozygotes and heterozygotes in a definite ratio. This has now been shown for the first time in man by J. B. S. Haldane and U. Philip (*J. Gen.*, 38, 193–200; 1939). They have analysed the data of relatives of hæmophilic patients listed in Birch's monograph. From daughters of hæmophilics there were 15 normal and 13 hæmophilics. Twenty-six sisters of hæmophilics were definitely heterozygous and forty-four could have been homozygous or heterozygous. Mathematical analysis shows that these figures are entirely reasonable and in accordance with the expectation that 50 per cent of the sisters of hæmophilics are heterozygous.

Genetics of the Rex Mouse

THE rex mouse has a coat somewhat similar to that of the same character in the rabbit. F. A. E. Crew and C. Auerbach (*J. Gen.*, 38, 341–343; 1939) show that rex is an autosomal dominant to normal. The caracul coat discovered by Dunn has very similar characters, but the authors show that caracul and rex are not controlled by allelomorphic genes. The similarity in the phenotypical characteristics of rex and caracul suggests that caution is necessary in assuming that parallel mutation in related species lies at the root of phenotypical similarity.

Sterility in *Drosophila melanogaster*

BERG showed that sterility mutations were more frequent in the X-chromosome of *D. melanogaster* than in all the other chromosomes put together. S. Prabhu (*J. Gen.*, 38, 177–191; 1939) has shown that in the X-chromosome the vast majority of sterility mutations occur in a small region between garnet and forked on the X-chromosome. This region had previously been identified as a locus probably related to sex determination by Goldschmidt and by Patterson and Suche. Whether the region is that of a sex gene is debatable, but the locus may be one containing several allelomorphs of sterility mutations.

The Avian Sternum

LARGELY due to the authority of Rathke and Parker, it is generally stated the avian sternum originates from rudiments derived from the ventral ends of the ribs. This view has not always been received without question, and the other point of view, put forward by Bruch so early as 1852, is that the ends of the ribs only secondarily fuse with the paired sternal plates. The matter has been reinvestigated experimentally by Honor B. Fell (*Phil. Trans.*, B, 563; 1939) using as material the embryos of the budgerigar. The sternum originates from paired rudiments which arise independently of the ribs and can be grown *in vitro* apart from either ribs or coracoids. It is suggested that the sternum should be regarded as related to the appendicular skeleton since its rudiments arise in close association with the wing buds. If a single rudiment is grown *in vitro*, it produces a half-keel but set at a wrong angle, and the presence of its fellow of the other side is necessary for the normal development of the keel. Even then, however, its growth-rate is slower than under non-experimental conditions and it never reaches its normal form. For this to occur development must take place with the normal relations of the surrounding tissues undisturbed. The junction of the two sternal plates is not due solely to their own expansion but to their displacement in a median direction.

Giant Fibres in Squids

IT is thirty years ago since L. W. Williams reported the presence of two giant nerve cells in the squid Loligo, but little attention has been paid to this observation since. Now, however, John Z. Young (*Phil. Trans.*, B, 504; 1939) has examined the structure of the nervous system of this animal in detail. It is found that the nerve fibres vary in diameter from $1\,\mu$ to nearly 1 mm., so that it is difficult to separate giant fibres from ordinary fibres. The author has paid particular attention to certain large fibres directly concerned with mechanism employed by the animal in shooting rapidly through the water. These fall into three groups, termed those of the first, second and third orders respectively. The fibres of the first order are two in number and arise from a pair of giant cells which may possibly represent the ventral portion of the pericesophageal ring of the ancestral mollusc. Each gives off a single axon which passes backwards to the palliovisceral ganglion, where it fuses with its fellow. Such an axonic fusion is a most unusual feature in animals. Fibres from this union make synaptic contacts with fibres of the second order. The fibres of the third order are syncytia formed by the processes of numerous neurons in the stellate ganglion. They receive numerous synaptic contacts from collaterals from the fibres of the second order. It is suggested that such a system is adapted for producing rapid movements rather than tonus. It is absent in the octopods, where the method of locomotion is entirely different.

Entomogenous Fungi

A RECENT paper by Mr. T. Petch (*Trans. Brit. Mycol. Soc.*, 23, Pt. 2; July 1939) makes a further contribution to knowledge of the fungi which attack insects. The present paper is one of a series which brings the total number of entomogenous fungi described by Mr. Petch up to 160. It has the usual yield of newly described species, this time nine in number. One of these, *Stemphyliopsis ovorum*, is not strictly entomogenous, but attacks the eggs of a snail in Ceylon. Other new kinds include *Entomophthora reticulata* from Great Britain, but the geographical range of the new records extends from Mauritius to Florida, and from the Gold Coast to Ceylon. One might, however, express a little disappointment at the provision of the two names *Hypocrella glabrescens* and *Aschersonia fimbriata* for two stages in the life-history of one of the new species. The first name denotes the ascigerous condition, and would seem to be adequate.

Santorin and Crete

N. A. CRITIKOS, of the Seismological Institute of the University of Athens, considers that the key to the downfall of the Minoan civilization in Crete and the "Descent of the Doriens" about the twelfth century B.C. is to be found in volcanic and seismic phenomena (*Bull. Volcanol. Ser.* (II), 4, 39–49; 1938). Between 2000 and 1500 B.C. it is thought that Santorin was in violent eruption accompanied by earthquake phenomena and sea waves on a large scale and that the original crater was then formed. (A repetition of this for which there are eye-witness accounts took place in September and October 1650.) Nor were Santorin and other areas in the eastern Mediterranean any more quiet in 1220 B.C. In the spring a violent earthquake was felt near Port Said and in the summer a shock was experienced at Wâdi-el-araba. In the spring of 1180 B.C. there were several shocks, including one felt at Jericho. It appears probable that at about this time Santorin again erupted and the sea flowed into the crater forming the large island and ring of small islands now visible. All this would be accompanied by the rain of ashes, sulphurous fumes, earthquakes and sea waves which would reach as far as Crete, destroying property and causing the deaths and injuries of numerous people. Repeated occurrences of this type would profoundly affect the life on the island. Critikos is further of the opinion that these natural phenomena were all part of a prolonged and more profound movement which resulted in the break up of the 'Egéide', forming the Cyclades, and which had repercussions on the whole of the eastern Mediterranean.

Periodic Comet Tuttle

JEFFERS and Moore observed this comet on August 12d. 11h. 20·2m. U.T. Its position was R.A. 5h. 55·8m., Dec. + 57° 22′; magnitude 18. In the *Handbook of the British Astronomical Association*, 1939, p. 32, there is an ephemeris computed by Dr. A. C. D. Crommelin; the true time of perihelion is 1·1 day later than that assumed by Dr. Crommelin. The positions in R.A. and Declination can be found by multiplying the correction coefficients by 1·1 and applying the results to the ephemeris.

Comet Kamensky

ON July 24d. 22h. 00m. U.T., Kamensky observed a comet. Its position was R.A. 20h. 55·0m., Dec. – 7° 00′. The object was described as diffuse, with central condensation, its magnitude being 7. An orbit has not been computed.

Law of Error and the Combination of Observations

H. R. HULME and L. S. T. Symms (*Mon. Not. Roy. Astro. Soc.*, 99, 8; June 1939) have developed a method which allows a system of continuous weighting to be found for a series of observations. When a comparison is made between experimental results for the distribution of errors and a Gaussian curve of the same probable error, it is frequently found that the large errors are much more numerous than the normal law indicates. This subject was treated fully by Simon Newcomb more than half a century ago, and quite recently Jeffreys has shown that the normal law is also defective from the theoretical point of view. Another defect of the normal law is that it affords no satisfactory criterion for retaining or rejecting apparently bad observations unless the observer has noted that the observation is not expected to be as good as the others. In the present paper the authors assume that they are dealing with a set of observations which are all of equal weight, so far as the observer knows. The problem is of a twofold nature: (1) the actual error law which best fits the residuals must first be found; (2) the system of weighting which corresponds to this law must then be obtained. Newcomb and Jeffreys have both solved the problem by different methods, and the paper shows that both of these lead to the same result in actual practice. A description of their method of weighting is followed by the results obtained. The residuals chosen for analysis are those found from the measurements of the variation of latitude made at Greenwich with the Cookson floating zenith telescope from 1927 to 1936. The method of weighting described has also been applied to the results of the measurement of parallax. While the improvement in the results of the latitude observations is small it is nevertheless appreciable, and no doubt the method will be applied in other lines of investigation.

A New Member of the Ursa Major Cluster

W. M. SMART (*Mon. Not. Roy. Astro. Soc.*, 99, 8; June 1939) shows that the star Gr. 1970 (G.C. 17919), apparent magnitude 6·74, spectral type *G* 0, is a member of the Ursa Major cluster. Hertzsprung suggested about seven years ago that the star was probably connected with the cluster, and Smart's calculations substantiate the view. The co-ordinates of the star for 1950·0 are R.A. 13h. 11m. 34s., Dec. + 56° 58′, and the proper motion components are μ_α 0·0135s., μ_δ – 0·035″. The total proper motion is 0·115″ in position angle 107·6°, the probable error of the latter being ± 1·6°, which is derived from the probable errors of the proper motion components. From his values of the co-ordinates of the convergent point Smart finds that the angular distance of the star from the convergent point is 132·3°. The calculated position angle is 99·9°, the difference of 7·7° between observed and calculated being only slightly greater than the largest difference found for stars belonging to the Ursa Major cluster. On the supposition that the star belongs to the cluster the calculated parallax is 0·039″, and the observed value, given in Schlesinger's "Catalogue of Parallaxes", is 0·045″ ± 0·009″. The calculated absolute magnitude is 4·70, which is the normal value for a *G* 0 dwarf, and the calculated radial velocity is – 12·8 km./sec., as compared with – 7·9 ± 0·9 km./sec. according to Moore's Catalogue and – 11·1 km./sec. determined by J. S. Plaskett at Victoria. The close agreement in all cases shows without doubt that Gr. 1970 is a member of the Ursa Major cluster.

INTERNATIONAL CO-ORDINATION OF DOCUMENTATION

THE growing realization on every hand of the importance of documentation to undertakings of every kind continues to be reflected in the attendance, papers and discussions at the International Conferences of the International Federation for Documentation. Founded as the result of an International Conference on Bibliography at Brussels in 1895, the Federation has become the recognized international organization for the discussion and co-ordination of methods and means for making available on demand the recorded facts relating to any and every subject of special study.

Although the Conference held at Zurich during August 10–14 last was one of the smaller so-called conferences of experts, which are held in alternate years between the full conferences of the Federation, some hundred and seventy members attended from seventeen different countries and thirty-nine papers were communicated, larger numbers than at many full conferences of the Federation in its earlier years. In expressing the welcome of the Swiss Government, Vice-Chancellor Dr. Leimgruber referred to the special importance of administrative documentation as a means of rationalization. Dr. Alingh Prius, president of the International Federation for Documentation, in reply appreciated the suitability of Switzerland, with its four languages, as an example of collaboration, and Zurich, as an industrial town, as meeting places for the Conference.

Four subjects were selected for special study at this Conference, and administrative documentation was one of them. In a paper entitled "La documentation administrative en Belgique", M. Daniel Warnotte gave a detailed account of the state of official documentation services in Belgium. He was followed by M. A. B. Boutillier du Retail of Paris, who referred specially to the French decree of 1938 creating a national centre of documentation at the Bibliothèque nationale for co-ordinating the whole of French administrative documentation. In his paper, "Notice sur l'unification des methods de classement dans les administrations publiques Belges," M. O. Molle of Brussels stressed the importance of the general adoption of a standard system of classification.

A typical paper was that by MM. E. Mathys, E. Rickli, C. Frachebourg and R. Calame of Berne, entitled "La documentation dans les Administrations Suisses des Chemins de Fer Federaux, des Postes, Telegraphes, Telephones et des Douanes," which gave a striking account of the advantages of co-ordinating the work of a number of administrative libraries. Documentation proceeds from the need of an organization to put in order the processes of collecting, abstracting, preserving and supplying books, articles, data, reports, public documents and archives. It has taken a long time to realize that, when such documents are properly collected, abstracted and made available, they are capable of affording invaluable assistance in administration. The existence of the gap between the making of a record in any sphere of work and the placing of that record in the hands of the individual who may need it, is proved by the number of individuals who set themselves to make notes of information that may be useful to themselves. There is as great a step between this and the creation of a special organization for the purpose, as there was for our ancestors, when they decided to give up baking their own bread and to let the baker do it for all. For good or for evil, the need has brought the means, and documentalists, like the bakers, have come.

The medium for distributing the records of progress is the periodical press, but it speaks in so irregular and incoherent a manner that it is impossible, without documentation, to obtain a clear and concise view of any particular branch of knowledge. Documentation is the remedy for the disorder that reigns in the production of documents. It enables a small country like Switzerland to avail itself of advances in knowledge and experimental results from all parts of the world.

In Switzerland, besides the National Library, there are some forty-nine libraries belonging to the Federal administration. The highly favourable results of co-ordinating the work of four of the larger of these libraries, namely, those of the Swiss Railways Department, the Post Office, the Telegraphs and Telephones Department and the Customs Department, has led to the serious consideration of a scheme for the co-ordination of all the administrative libraries in the country. For these four libraries, the acquisition, care and manipulation of books and periodicals is centralized in one library. Thus all the material of documentation, within the scope of the administrations concerned, is collected and dealt with in one place according to the best principals of librarianship and documentation. Each official knows where to go without delay for his material and information. Purchases are made systematically, without duplication. There is economy of cost, staff, furniture, apparatus and material. A community of work between the libraries is recognized, about which there is constant consultation, mutual advice and help. Each library retains its own special character and borrows books freely, as required, from the associated libraries. Periodicals pass from one library to another, or to local branches, sometimes at the rate of thirty an hour.

Since officials usually require documents relating to a particular topic rather than by a given author, a subject catalogue is needed, which must be very minutely subdivided. The Universal Decimal Classification has been adopted by all four libraries as being the most appropriate, thus becoming the basis of mutual co-operation. There are also author and various special catalogues.

In recent years the Swiss Government has realized the inefficiency and costliness of making a documentation of each subject as it arises, and a central documentation service has been organized for these Departments. Periodicals necessarily form the basis of this service. As these come in, data and other useful information are abstracted from them and entered on cards, which also are classified by the Decimal Classification. The cards are retained by the individual libraries, the Post Office having

10,000, the Telegraphs and Telephones centre 80,000 and the Railway Department 200,000. Mutual interchange is facilitated by the utilization of standard methods. The good results obtained could not have been achieved otherwise than by such a rationalization and are such that the same principles are likely to be extended to all the Swiss administrative libraries.

The Section devoted to the Division of Work between Libraries and Documentalists attracted some very interesting papers. Mr. A. B. Berthold gave a survey of work on Union Catalogues in the United States in a paper entitled "Union Catalogues and Documentation". There are now forty-six such catalogues in various stages of completion in the United States. One is national in scope, with approximately 10,000,000 cards; 22 catalogues relate to library holdings in various regions; and 23 are devoted to works in large subject groups. The Federal Government's policy of providing free labour has been the chief factor in their growth, and microphotography has become the unchallenged basis for all such work. Besides indicating the location of books, union catalogues are useful in tending to standardize cataloguing procedure. But, as all such catalogues are arranged under authors, they are unable to provide any answers to inquiries for books on particular topics.

An able paper, "Aufgaben der Bibliotheken in Rahmen der Dokumentation", was contributed by Herr C. Walther of Aix-la-Chapelle. The library problem is to collect systematically the literature within its scope as completely as possible and to make it as fully available as possible to its users. For purposes of documentation, a complete collection of the world's output of useful literature, especially periodicals, is most important. The best aid to users that a library can provide is a complete catalogue of its holdings, with exact information of every part received. A detailed subject catalogue is also necessary. For the utilization of the material in the library, bibliographies and abstracting journals must be added. Since many librarians are born bibliographers, libraries can also serve their users by preparing bibliographies on special subjects within their scope.

In a paper entitled "Bibliotheken und Dokumentation", M. S. Dahl of Copenhagen stressed the need of the investigator for efficient documentation, and showed the difficulty of drawing a sharp line between the work of the librarian and the documentalist. In a similar strain, M. Henri Lemaître of Paris referred in his paper on 'La documentation et les bibliothèques", to the address to the International Committee of Libraries at Brussels last year by M. Marcel Godet, president of the International Federation of Associations of Librarians, who had pointed out the close relationship between the work of librarians and documentalists. Librarians are concerned more with intellectual culture, while documentalists are interested more particularly in utilitarian considerations. Theoretically, documentation includes all, and librarianship is only a part; actually, documentation is a young movement, while librarianship is already full grown and can contribute much to the assistance of documentation.

Mr. Lancaster Jones, London, discussed the part libraries can play in the task of technical documentation, showing how an elaborate organization is needed to discover even the existence of a considerable portion of the world's technical literature. By making its collections as complete as possible within its scope and issuing periodical catalogues, classified by subject, of its accessions, a library can perform an invaluable service to documentation. To this can be added a contribution towards a co-operative scheme for the complete subject-indexing of articles in the periodical literature.

The discussion in this Section led to the conclusion that, while the work of librarians is more passive and that of documentalists more active, no sharp line can be drawn between them, and the solution can be found only through the most complete collaboration.

Space does not permit mention of the papers of equal value that were contributed to the other two sections of the Conference, dealing, respectively, with Documentation in Industry and Photographic Reproduction Methods for Documentation Purposes. The whole are published in a volume and supplement entitled "Rapports: Fédération internationale de Documentation, XVième Conférence, Zurich" (10 Swiss francs) and obtainable from the International Federation at Willem Witzenplein 6, The Hague, Netherlands. These should certainly be studied by all librarians and documentalists as well as by all those who are interested in the accessibility of information.

Finally, it must be mentioned that not the least factors in the success of the Conference were the delightful hospitality and kindness shown by its organizers.

RHYTHMIC PROCESSES IN BIOLOGY

THE second conference of the Internationalen Gesellschaft für Biologische Rhythmusforschung was held in the "Stads.-en Academische Ziekenhuis" in Utrecht (Holland) on August 25–26. In spite of the international situation the meeting was very successful, and papers were read by members from Holland, Germany, Sweden, Russia and Britain. The German language was used for the most part, but communications were also made in English and French.

The conference was opened by Dr. E. Forsgren, of Stockholm, the president of the Society. On the first day the papers covered a wide range of subjects. Prof. F. Linke (Frankfort) dealt with the different rhythmic processes measured by the meteorologist and which may be important to the biologist. Prof. R. Stoppel (Hamburg) described her work on leaf-movements in plants in relation to time and other factors. F. H. Stieltjes (The Hague) discussed some interesting examples of rhythmic activity. Prof. van der Pol (Eindhoven) considered the mathematical aspects of certain phenomena, and showed by means of a most ingenious electrical model how it is possible to produce artificially the electrical changes associated with normal and abnormal heart beat. K. Mellanby (Sheffield) described the periodic activity of two insects, the bed-bug and the cockroach, under natural conditions. P. Schoorl (Bennekom) spoke on the curious way in which the rate of increase in weight of pigs fluctuates in an apparently rhythmic manner.

The second day of the conference was devoted mainly to papers dealing with the importance of rhythmic processes in medical physiology and medical practice. Communications were made by Hj. Holmgren (Stockholm), A. Jores (Hamburg), F. Gerritzen (Lunteren), J. Möllerström (Stockholm), Prof. R. Hopman (Cologne), W. Menzel (Tübingen), M. Arborelius (Halmstad), and E. von Philipsborn (Oberstdorf). Lively discussion followed every paper.

It has been arranged that the papers given at the conference will be published in a special supplement to the *Acta Medica Scandinavica*. The future of the Society was discussed at some length. Most of its members are mammalian physiologists or practising physicians, and some zoologists and others were in doubt as to whether their work was of real interest to these medical workers. It was almost unanimously decided that all investigators whose problems dealt with questions of rhythmic activity would be likely to learn a great deal from discussion of each other's work, and it was decided to make an attempt to increase the membership of the Society. It is particularly hoped that more British workers will join; further particulars may be obtained from the secretary, Dr. Hj. Holmgren, Karolinska Institutet, Stockholm.

The local arrangements for the conference were made with great efficiency by Dr. F. Gerritzen of Lunteren, and excursions, dinners, etc., were all greatly enjoyed. Members of all nationalities, including those which are now unhappily at war, were able to discuss their work in a particularly friendly atmosphere.

KENNETH MELLANBY.

PROBLEMS OF GROWTH AND DIFFERENTIATION

AT North Truro, a small village near the extreme end of Cape Cod in Massachusetts, a remarkably successful conference on problems of growth and differentiation was held during August 7–11. Sponsored by the editorial board of *Growth*, members of which also carried out the excellent local arrangements, it brought together about seventy workers from the fields of genetics, embryology, biochemistry, morphology, and botany. Many were accommodated in the wooden cabins of Whitman House, at the edge of a pinewood, not far from excellent sea-beaches, and the delegation from England, at any rate, appreciated to the full the hot weather and the sunshine. The meetings took place in the village school, a building in the attractive wooden New England style, admirably adapted for the purpose. Some informal discussions also took place in the Marine Biological Laboratory of the Lankenau Hospital, about half a mile away.

Each morning and afternoon began with a lecture lasting about an hour, and followed by unhurried discussion and comment. The opening session was devoted to a lively discussion of the proper definitions of growth, differentiation and determination, following a paper on growth and cell-division by Dr. Warren Lewis (Bar Harbor), who illustrated his points by a number of films. In the afternoon Dr. P. W. Gregory (Berkeley) gave an account of the body of work which has shown a relationship between hereditary size in mammals and glutathione content of the tissues, though the connexion does not seem to be so clear in the case of birds. As regards its meaning, an action of sulphydryl groups on synthetically acting proteases seems the most probable hypothesis. The general connexion of $-SH$ and growth or cell-division also came in for discussion.

The second day was given over to the relations between genetics and embryology. In the morning Prof. Curt Stern (Rochester) contributed a masterly description of the present position, dealing with the time of action of genes, dependent and self-differentiation, nuclear induction, etc. He pointed out that dependent differentiation may not always be due to the diffusion of substances; but that in some cases the migration of cells themselves may be involved. Particular interest was aroused by his summary of recent work showing that, in plants also, transplantation experiments reveal nuclear inductors. In the afternoon, Dr. C. H. Waddington (Cambridge, England) took up the story in relation to *Drosophila* development. After making a distinction between form and matter which later gave rise to some argument, he developed the interesting fact that when in a mutant organism, an organ develops in the 'wrong' place, genes which normally act upon such organs can act just as well though the relation of part to whole is abnormal; or in a 'monstrous' part, such as a structure which is proximally a leg and distally an antenna, leg-genes and antenna-genes still exert their characteristic effects. The meeting closed with an animated discussion of the problem whether the 'deployment of competences' of the English school is really the same as the 'segregation of potencies' of the Americans or not.

On the third day, biochemical problems were taken up. Dr. J. Needham (Cambridge, England) described the progress which has been made during the last ten years in our knowledge of the chemical aspects of organizer phenomena. For reasons of time, the discussion was almost entirely confined to the Amphibia. The basic difficulty in these investigations, he said, which had not been at all anticipated at their beginning, is that the competent ventral ectoderm, on which alone the power of a substance to evoke neural differentiation can be tested, itself contains the natural evocator in masked or inactivated form, as can readily be shown by denaturing its proteins in any way and implanting it into another embryo. That adult tissues probably all contain the primary evocator can be shown by the fact that in many cases denaturation of their proteins is not necessary. Recent work on the metabolism of the different regions of the gastrula, which should throw light on the liberation of the primary evocator, was also considered in detail. In the afternoon, the chemical aspects of later growth were described by

Dr. Otto Glaser (Amherst) who introduced the conference to a new method of formulating the growth of organisms and their chemical constituents.

The last full day opened with a highly stimulating paper from Dr. Schotté (Amherst) on regeneration. After briefly reviewing the old question of the origin of the material of the regeneration blastema in invertebrates and vertebrates, he went on to deal with the vexed but important problem of the 'totipotency' of the regeneration blastema in Amphibia. Admitting that limb-competence in the tail-blastema or vice versa has not as yet been definitely proved, he went on to describe his remarkable experiments which indicate that lens-competence, though long absent from the body epidermis, reappears in the material of the tail blastema. It seems also to reappear in regenerating epidermis over the eye. Notochord implanted in tail blastema has also induced pronephric and neural tissue. Should these findings be further confirmed and generally received, a new word will be needed to describe the return of competence after its ontogenetic disappearance. From the floor of the house the word 'recuperation' was suggested, and this seemed to find some favour. In any event, as Ross Harrison has pointed out, there are undeniable instances of reversals of determination, as in tunicates, so the return of competence in vertebrates would not be quite unexpected. The afternoon session on this day was devoted to the studies of Dr. Sinnott (New York) on gene-controlled shape in cucurbitaceous fruits; this led to a vigorous discussion of field-concepts, which had been brewing during former sessions.

On the last morning Dr. Woodger (London) explained the advantages which would accrue to biologists in framing their theories if use was made of logistic technique, of which he gave some examples. He also directed attention to certain points of interest for biological theory which had arisen during the meetings.

On the whole, the meetings were remarkable for the degree of unanimity of thought on fundamental problems which prevailed, as perhaps must be the case when there is enough time to explain individual points of view in a spirit of moderation and candid sincerity. Apart from those who contributed lectures, the discussions were greatly enlivened by the presence of such workers as Dr. Berrill (Montreal), Dr. Hoadley (Harvard), Dr. Thimann (Harvard), Dr. Paul Weiss (Chicago), Dr. Frank Daniel (Berkeley), Dr. Barth (New York), Dr. Reimann and Dr. Hammett (Philadelphia) who showed a film illustrating differentiation and dedifferentiation in Obelia, Dr. L. C. Dunn (New York), Dr. Samuel Brody (Missouri), Dr. Hamburger (St. Louis) and Dr. Frank (New York). At the end of the conference suitable steps were taken to form an organization able to call together similar conferences on growth and differentiation in future years.

TABOO*

THE use of the word 'taboo' in anthropology for customs all over the world, which resemble in essentials the reference adopted from Polynesia, seems undesirable and inconvenient. For such customs the terms 'ritual avoidance' or 'ritual prohibition' are proposed, defining them by reference to two fundamental concepts, 'ritual status' and 'ritual value'. A ritual prohibition is a rule of behaviour which is associated with a belief that an infraction will result in an undesirable change in the ritual status of the person who fails to keep the rule; that is, it involves the likelihood of some minor or major misfortune which will befall the person concerned.

Anything which is the object of a ritual avoidance or taboo may be said to have ritual value. The ritual value is exhibited in the behaviour adopted towards the object or occasion in question—not only in the negative ritual, but also in the positive ritual. A large class of positive rites, those of consecration or sacralization, have for their purpose to endow objects with ritual value.

The word 'value' as thus used always refers to a relation between a subject and an object. It may refer to the act of behaviour towards an object. A social system can be conceived and studied as a system of values. A society cannot exist except on a basis of a certain measure of similarity in the interests of its members. In terms of values the first necessary condition of the existence of a society is that the individual members should agree in some measure on the values that they recognize. To avoid misunderstanding it is necessary to add that a social system also requires that persons should be objects of interest to others.

The study of ritual may be approached by the consideration of the purpose or reasons for the rite, or by a consideration of its meaning. A third method is by consideration of the effects—the direct effect on the person concerned, which may be termed the psychological effect, and the secondary effect on the social structure, the network of social relations binding individuals together in an ordered life—the social effect. By consideration of these we may succeed in defining the psychological function, and in discovering the social function of a rite.

The rites are readily perceived to be symbolic. The immediate psychological effect can to some extent be observed by watching and talking to the performers. The ostensible purpose is present in their minds, but so also is that complex set of cosmological beliefs by reference to which the rite has a meaning. In the performance of the rite the native has made a contribution to the maintenance of the order of the universe, of which man and Nature are the interdependent parts.

Assuming that the act is symbolic, what method, other than that of guessing, is there of arriving at its meaning? We may start with a general working hypothesis that when in a single society the same symbol is used in different contexts, or on different kinds of occasions, there is a common element or meaning, and that by comparing the various uses of the symbol we may be able to discover what the common element is. Thus taking certain customs of avoidance in the Andaman Islands, it would appear that the common element is that the individual affected is in an abnormal ritual status and is likely to suffer some misfortune unless certain prescribed ritual precautions are observed, such as the avoidance of certain foods, while friends or others avoid the use of the individual's personal name. By means of these taboos the occasion acquires a certain social value. But while these rites give men confidence, comfort, and a sense of security, they might equally cause fear, that is, from black magic or spirits. It is largely by the sharing of hopes and fears that human beings are linked together in temporary or permanent associations.

---

* From the Frazer Lecture, 1939, by Prof. A. R. Radcliffe-Brown. Cambridge: At the University Press, 1939. Pp. 48. 2s. 6d. net.)

The symbolic rites of the Andamanese are the obligatory recognition of a standardized symbolic form of the significance and importance of the event to individuals and the community at large. They serve to fix the social value of occasions of this kind. So with the food taboos, they attach a definite social value to food, and it is in the activities connected with the getting and consuming of food, with their daily instances of collaboration and mutual aid, that there continually occur those inter-relations of interests which bind the individual men, women, and children into a society. This may be generalized under the formulation that the primary basis of all ritual, and therefore of all religion and magic, is the attribution of ritual value to objects and occasions which are either themselves objects of important common interests linking together the persons of a community or are symbolically representative of such objects.

ECONOMIC BOTANY IN THE TROPICS

SIR FRANK STOCKDALE, in his interesting address, on "The Application of Economic Botany in the Tropics", which had been prepared for the Dundee meeting of the British Association but was not delivered owing to the cancellation of the meeting, points out that many of the economic crop plants now commonly grown in the tropics were distributed when new lands were discovered in Elizabethan times. Tobacco, for example, from tropical America; sugar cane and the banana from the Old World; cacao from Central and South America, and rubber from Brazil. Coffee is indigenous in tropical Africa, and China and Cochin China appear to be the original home of the citrus group.

Following early haphazard distribution came the introduction of Cinchona to India by Markham and Ledger and of rubber to Ceylon by Wickham, both through the auspices of the Royal Botanic Gardens, Kew.

The introduction of coffee to Ceylon and the outbreak of coffee-leaf disease there resulted in arousing scientific interest in tropical crops. Had Marshall-Ward, who went out to investigate the disease, had available the important research work on the rooting systems and the effect of light on the stomatal mechanism in *Coffea arabica*, which Nutman has recently done at Amani, it is possible the Ceylon coffee industry might have been saved.

The West Indian sugar cane industry was similarly faced with disaster through disease, but, thanks to the work of Harrison and Bovell in raising seedlings from different varieties of *Saccharum officinarum*, new types—'noble canes'—were introduced and disease-resistant strains raised. This work, continued by Barber at Coimbatore, India, has been carried on successfully there under Venkataraman and by the Dutch workers in the Netherlands East Indies. *S. spontaneum* has been used in crossing, as well as other allied species, and valuable canes have resulted, notably the well-known *P.O.J.* 2878 which came from a third 'mobilization' of *S. spontaneum*. Types of cane suitable for different types of soil have also resulted from these cross-breeding researches.

Sir Frank then deals with the cotton crop and the valuable work which has been done in Egypt, the Sudan, India and the United States, etc., which have resulted in marked improvements in yield, lint length and fineness, and strength of lint, while disease resistance has also received much attention with valuable results.

Both Cinchona and rubber have been subjected to careful scientific investigation which has led to the recognition of high- and poor-yielding strains, and the selection of high-yielding 'mother-trees' for budding. Hybridizing work on rubber is now being carried out and a search is being made also for strains resistant to the Oidium mildew which is causing serious damage to rubber in the East.

The work now in progress in Trinidad with cacao is fully dealt with and the important discovery of incompatibility in cacao is referred to. Unfortunately it has now been found that some of the best yielding strains are self-incompatible, which upsets some of the earlier work, though the discovery has enabled the work to be prosecuted on fresh lines.

Sir Frank finally deals with the work that is in progress in the improvement of rice and other crop plants and with the work at Amani on raising strains of Cassava immune to mosaic disease.

He concludes with the following very apposite remarks:

"The breeding of resistant forms is the most effective method by which to overcome the difficulties facing producers, and co-operative work by plant breeders and pathologists is required if a satisfactory solution of the present-day problems is to be found.

"Improved types of crop plants, however, demand higher standards of agriculture and whilst it is to be expected that improvements may be achieved from further collections of wild forms for special breeding work and from the interchange of strains which have already been evolved, sound developments are likely only to be secured by a general advance in methods of husbandry designed to ensure soil conservation and the maintenance of its fertility, and by the adoption of those agricultural systems which are suited to the particular environment. In this field much work still remains to be done and additional teams of research workers with specialized training are required in the approach to the problems which are presented to those who are responsible for the welfare of the Colonial Empire."

SCIENCE NEWS A CENTURY AGO

Steam Navigation to the West Indies

A FURTHER step in the promotion of trans-Atlantic steam navigation was taken on September 26, 1839, when the Government granted a charter to the Royal Mail Steam Packet Company which was formed to connect Great Britain and the West Indies by steam. By a contract made in 1840 with the Admiralty, the Company agreed for the sum of £240,000 per annum "to provide, maintain, and keep seaworthy, and in complete repair and readiness, for the purpose of conveying all Her Majesty's mails, a sufficient number (not less than fourteen) of good, substantial and efficient steam-vessels, of such construction and strength as to be fit and able to carry guns of the largest calibre now used on board of Her Majesty's steam-vessels of war, each of such vessels to be always supplied with first-rate appropriate steam engines of not less than 400 collective horse-power; and also a sufficient number (not less than four) of good, substantial and efficient sailing-vessels, of at least 100 tons burden each".

Climate of Russian Possessions in America

IN a long notice of Von Baer's report on the climate of the Russian possessions in America, the *Athenæum* of September 28, 1839, said: "There is no philosopher of the present day to whom Physical Geography (a branch of knowledge fast rising into vigour) is more indebted than M. Baer. . . . In 1830 the Baron F. von Wrangel, well known for his scientific exploration of the northern coast of Siberia, was appointed governor of the Russian possessions in America. In the course of last year Baron von Wrangel placed at the disposal of the Imperial Academy of Sciences at St. Petersburg, all the papers relating to the north-west coast of America . . . and from these papers the learned academician M. Baer immediately selected the Meteorological Journal for the subject of his comments." The observations were made at New Archangel on the southern Sitka Island (named in some maps Baranov Island) and von Baer made a comparison of the mean temperatures of that place with others in the same latitudes. "As the comparison exhibits in the broadest light that apparently anomalous contrast of climate in which it is the business of the physical geographer to trace the operation of constant laws, we shall here state the problem in the form of an abridged table:

Mean Temperatures

	New Archangel	Middle of the Continent	Nain on coast of Labrador	Bergen in Norway
Lat.	57° 3 N.	57°	57°	60·24°
Long.	135° 13 W.	108°	61·20°	—
Winter	34·7°	−4°	−1·2°	36°
Spring	42·2°	27·2°	21·6°	44·6°
Summer	56·8°	66·2°	45·6°	58·5°
Winter	47·8°	30·7°	36°	47·7°"

Friedrich Mohs (1773–1839)

ON September 29, 1839, Friedrich Mohs, the German mineralogist, died at Agardo, near Bellumo, Italy, at the age of sixty-six. Born at Gernrode in the Hartz Mountains on January 29, 1773, he was educated at Halle and at the Mining Academy at Freiburg, which had been founded in 1765 and of which the famous Abraham Gottlob Werner (1749–1817) was then the inspector and teacher of mining and mineralogy. From Freiburg, Mohs went to Austria to study further and in 1815 became professor of mineralogy at Gratz. In 1817 on the death of Werner he returned to Freiburg as professor of mineralogy, holding the post for nine years, after which he was transferred to the Imperial Academy, Vienna. Mohs was one of the originators of the crystallographic systems. His "Treatise on Mineralogy, or the Natural History of the Mineral Kingdom" was translated into English by William Haidinger and published in Edinburgh in 1825.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

METEOROLOGICAL OFFICER CADETS (Male) in the Department of Industry and Commerce—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (September 28).

ASSISTANT AIRCRAFT INSPECTOR, Grade I, in the Civil Aviation Directorate of the Government of India—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointments 5/1B) (October 14).

HEADMASTER OF HARROW SCHOOL—The Chairman of the Governors of Harrow School, c/o G. F. Finch, Clerk to the Governors, 70 Pall Mall, S.W.1 (October 16).

DIRECTOR OF STUDIES for the Anglo-Yugoslav Institute, Belgrade—The British Council, 3 Hanover Street, W.1 (quoting 'Yugoslavia').

SCIENCE AND SOCIAL PIONEERING

THE first British and American Association Lecture was to have been delivered at Dundee on September 5 by Dr. Isaiah Bowman, who had chosen the title "Science and Social Pioneering" for his lecture. Circumstances prevented its delivery, but it is available in printed form, and it provides a thoughtful analysis of views on the contribution of science to social welfare and to that process of continuously planned advance across the threshold of experience which may well be called social pioneering.

The opinions as to the extent to which science has added to man's cultural possibilities, given him a better way of thinking through his difficulties, or raised his hopes for a more ethical civilization, which Dr. Bowman has collected from American sources outside the ranks of science, are largely to be met in Great Britain and in France also, both within and without the ranks of scientific workers. Science, it is at last being realized, is a part of human life, not something separate and distinct As human experience, it is not universal, a summation of knowledge applicable and useful to the whole of life; it is rather a thing of limited categories, a special form of human interests.

To most men of science, science is only a specialized form of experience, but the study of the background of social life against which science has developed raises problems foreign to this outlook. Any serious attempt to probe back to the social origins and social consequences of scientific discovery demands that scientific workers shall at least make an effort to guard against the dangers of their own specialization. To be fully scientific, they must be aware not only of their own point of advance but also of the advancing front of science.

We should not indeed despise specialization, and Dr. Bowman points out that specialization has increased the satisfaction of many of our fundamental material needs. If the spiritual gains at the moment seem in deplorable contrast to the material benefits, it should be remembered that one of the greatest achievements of science is its emphasis upon free inquiry—the mind itself in command, driven by curiosity and the sense of adventure. Civilization itself can well be considered an adventure in change, and science has become one of the greatest adventures of our time, partly because it deals with the edge of the possibilities. Man is changing his own possibilities as well as those of his world as he goes along. He is at the centre of his own creative experiment. What science supplies is not at all an addition, positive and beneficial, until men have proved it so, and with the addition of things and forces, social and natural, good and bad, ever new possibilities are emerging.

This insistence on the spirit of adventure is indeed one of the keynotes of Dr. Bowman's address. The new frontiers opened up by science in old communities make demands on the spirit of man not less than those made in the pioneering days in a new continent. The play of forces involved in the far-reaching movements and cultural changes of a scientific age, whether self-initiated and free or guided by government, represents a development of high interest in the social field. Vital leadership, courage and local pride as well as equipment and the experimental point of view are required.

Moreover, we have to remember that what we gather of scientific knowledge concerning society and how it might be improved form one set of data; to persuade or to exercise control to bring about desired ends is quite another. Society is built upon beliefs, traditions, prejudices, suppositions and philosophies as well as facts, institutions, inventions and material—all supported by power or force exercised through time. Every advance in applied science calls for a tighter and more inclusive social organization, and while in democratic countries the adoption or rejection of ideas may be freely debated or contested, it is premature to suppose that even democracy ensures continued freedom.

What Dr. Bowman terms social pioneering is concerned with culture in the making, with environment that becomes understood through thinking about the conditions of trial and the effects of error. It deals with new social forms or old forms adapted to new situations, and becomes ever more complex and overpowering for the individual. Such conditions naturally make planning more uncertain, because of unpredictable turns and their effects, unforeseen impacts or disturbances; and the risks in social planning are accentuated if attempts are made to accelerate it, as in an emergency, without due regard for the time-factor.

None the less, the first duty of an intelligent society in this age is to seek out the causes of things. The scientific method is nowhere needed so much as in the sorting-out of causes and the recognition of the action of the forces supposed to be at the root of our troubles; the first step, however, must be the scientific study of the field of science itself and the conscious planning of policy and research with regard to the social needs of the period and the social functions of science. We cannot be sure that more scientific knowledge will resolve the conflicts between classes, reduce the arrogance of nationalism and diminish the chances of war, but we can at least hope that it will assist in providing a more even-tempered attitude and greater readiness to accept findings even when they involve the disturbance of sectional interests.

Social forms, as Dr. Bowman reminds us, cannot keep pace with creative thought. A time lag is inevitable, because we have found no way to teach and test ideas except through time-consuming and often inconclusive experience, and no one branch of study can solve the whole array of problems of a people. Much more could be done, however, by combined effort on the lines of the team-work which in industrial problems, for example, has yielded brilliant results through the efforts of workers in different branches of physical science concentrated on a single objective. The realization by an increasing number of scientific workers to-day that social action is imperative if freedom of thought and investigation are to be preserved for science itself already provides a stimulus This consciousness is gradually overcoming the reluctance of those who fear the introduction from politics of bias or prejudice, for the pace at which events move demonstrates that even inaction has political consequences.

The formation of the new Division for the Social and International Relations of Science is one of the most significant recent expressions of this urge to advance science beyond the mere study of Nature at the level of inanimate Nature to the level of men in their group activity. Dr. Bowman's address attempts no positive and final answers as to the solutions of many of the problems thus opened up before us, but his presentation of man's endless adventure in progress reminds us that science is our greatest inspirer of hope. Even in these sombre days of anxiety, it holds out the rational hope that the triumphant methods that have given us deeper understanding and increased efficiency as biological and social mechanisms, will one day give us a still deeper insight into the nature of man and what he may become under rational control.

What gives special pertinence to Dr. Bowman's insistence on this element of pioneering and invention is the change in the nature or emphasis of scientific method. Just when concern with the impact of science on society and with the effect of society on science itself is growing within the ranks of science, scientific workers are coming to realize that there are limits to the extent to which the scientific method of isolation in experiment can be even approximately used. The widening front of science synchronizes, as Prof. H. Levy has pointed out, with the necessity for a drastic change in scientific method itself. It is not merely in social science that the experimenter must become an integral part of the process itself.

The wider view of scientific method, which recognizes the limits within which even a statistical validity can be given to simple repetition, and admits that every scientific experiment is a piece of scientific history and therefore a piece of social history, compels us also to recognize the inter-relation of all phenomena and to see the role taken by each element in relation to every other. In scientific work, failure to appreciate fully dialectical change may have comparatively slight consequences; the social repercussions of failure to appreciate the dialectical changes produced by and on science in its interaction with society may be almost catastrophic.

Because we do not in general take a scientific view of the processes of change that are manifested in society, and because men of science themselves fail to see that the scientific method requires qualitative transformation before it can be applied to the active handling of those issues, we tend to become mere passive onlookers in a course of events which it should be the first scientific duty of all men to control as they ultimately would control any laboratory process.

The address prepared by Dr. Bowman appeals to the characteristic scientific spirit, which cannot rest with unexplored fields before it. The realm of social action itself is the new laboratory, and the steps towards the control of social processes—the taking of political action and the making of social history—are, first an understanding of the interplay of cause and effect in the sense of the new statistical and dialectical method, and then a decision on the new processes which are to be brought into play to transform the situation qualitatively. In this new and wider field, science will yet forge new and appropriate techniques and wield them as effectively as in the physical domain itself.

FISH MOVEMENTS AND FISHPASSES

La mécanique du poisson de rivière
Qualités nautiques du poisson; ses méthodes locomotrices, ses capacités; ses limites; résistances du fluide; effet de la vitesse, de la pente; résistance de seuil. Par G. Denil. Pp. 395. (Bruxelles: Goemaere, Imprimeure du Roi, 1938.) n.p.

SOME thirty-two years ago, G. Denil, at that time chief engineer of Belgian Public Works, stood by a new weir, 3·5 m. in height, and lacking a fishpass of any kind whatever. As he watched the tail water of the dam, he was struck by the frantic and necessarily unsuccessful efforts of many salmon to surpass this obstacle by leaps, and also their wholesale destruction following exhaustion, by their overcrowding in a restricted channel, and at the hands of fishermen who had no difficulty in capturing their helpless prey.

On thinking over the complex problems which were involved, Denil resolved to seek a full understanding of the conditions necessary for the protection of migratory fishes, and to construct fishpasses so economically that they might become integral parts of all weirs which interrupt the upstream passage of the migrants. So early as 1909 he was able to describe in a long and exhaustive paper his first new successful fishpass, based on the principle that the obstacles involved are oblique to the main waterflow and are spaced so closely that, instead of creating alternate pools and waterjets, they derive secondary streams from the main flow, so that the abrupt re-entrance of these streams causes an energy dissipation of considerable intensity.

Subsequent to the publication mentioned above Denil constructed and controlled a number of fishpasses of exactly the same type and proceeded to improve his system, keeping always in mind the combination of theoretical considerations and of laboratory experiments with observations of the successful control of the passes already in operation. Until 1936 he published very little on the subject of his work. In that year he began a long series of articles published in the *Annales des Travaux Publiques de Belgique*. These articles are brought together in the present book, the title of which, though long, still gives an inadequate indication of the contents.

The first chapter relates to structural features of salmon-like and elongated white fish. The second contains an analysis, depending to a large extent on the basic work of Breder, of their various types of locomotion; swimming against the stream; jumping; and driving with the stream being particularly considered. In the third chapter, the eel and its locomotion are discussed, comparisons being made with matters already considered and also with the sea lampreys. In the fourth chapter, the author describes his own experiments on the velocity-resistance of fish-like bodies. In his fifth chapter, he reports on his own measurements and on those of Kreitman and others regarding the greatest *relative* velocity of fish swimming against a stream, that is, on the 'limit of swimming velocity'. He adds, however, that to attribute *direct* and decisive importance to this limit, is to accept by implication the hypothesis—never previously stated explicitly, but certainly not questioned either—that the swimming ability is adequately defined by the relative velocity V, or, that the longitudinal component of the weight G of a fish is, in so far as its locomotive effort is concerned, neutralized by the corresponding component of its buoyancy. The three succeeding chapters are devoted to the difficult task of disproving this hypothesis and to proving that the actual locomotory effort or force F_1 is equal to the velocity-resistance plus the resistance directly due to the slope, and

$$F_1 = Z\,\frac{V^2 F}{2g} + G \sin\alpha, \text{ where } \alpha \text{ is angle of slope.}$$

It would lead far afield to review in detail the author's experimental and theoretical arguments in support of his surprising thesis. Suffice it to state that his evidence, though challengeable on several points, appears on the whole to be fairly convincing. In any event, even the most doubting critic would have to admit that the thesis deserves thorough and systematic study*. Until this has been done, the thesis as a whole must be accepted as a 'working hypothesis' in the practical tasks of fishpass design and in preference to the older one. These three chapters offer particularly stimulating reading, because a number of very different problems of hydraulics and geophysics relating to a steep water surface are employed in analogy.

In the ninth chapter the author turns from discussing a fish as a 'body' in the purely mechanical sense of the word to considering a fish as a living creature. He analyses questions both of the biology and the psychology of fish migration, showing that different species have marked differences in the conditions and 'motives' for their migratory efforts. This chapter will be of much interest to ichthyologists. Some of the views which it expresses may also lead to useful discussions.

Following these preparatory chapters, the author tackles the main problem around which his work is centred, namely, the quantitative study of the mechanical force or locomotory effort, F_1, of which a fish is capable when swimming continuously for a period of about one minute. It is obvious that if one knows the total resistance which a fish encounters in some particular steep channel, and that if one notes which fish pass the channel without difficulty, which pass after a struggle, and which entirely fail to pass, the full data required for the determination of the limiting value of F_1 are known. This is exactly what Denil does in Chapters x and xi. In addition, he makes some less exact but still fairly reliable inquiries into the limiting force F_2 which a fish is able to develop over a very short distance (for example, in jumping, or in facing a local pitch-velocity). The result of these inquiries is to show that the limiting value of F_1 varies between 0·5 G and 0·7 G; that of F_2 varies between G and 1·4 G. These latter results may be compared with those of Houssey; and although the agreement proves to be very rough, it is nevertheless remarkable, not only in view of the difficulty of the question and the complete independence of their work, but also by reason of the fundamental difference in the mode of approach of these two investigators.

These two chapters are probably the most important in the book because the author, having inquired into the limiting force F_1 for fishpasses constructed by himself according to his old but now improved principle of energy-dissipation, now gives a short account of these newer designs. Their distinctive feature, as compared with his earlier models, is that both the normal cross-section of the channel and the 'obstacles' are so shaped that the pressure losses of the secondary streams, both at their beginnings and along the secondary channels, are reduced as much as possible so that *vigorous* secondary streams, at their re-entrance, dissipate the energy of the main stream. It is regrettable that only summary information is given by the author on his theoretical ideas and on the very extensive experimental studies on which his designs are now based. In these chapters also the question of arranging the downstream end of a pass is touched upon, and an original contribution is made towards the solution of this difficult matter

Chapter xii discusses the reduction of slope necessary if the single 'flight' of a steep fishpass between two resting pools is of greater length than that which may normally correspond to a one minute passage.

Chapters xiii and xiv are concerned with the difficult task of offering a rational theory for the choice of dimensions for the ordinary pool-and-jet fishpasses in accordance with the rules laid down in Chapters x–xii for Denil and similar fishpasses. The basis of this theory, which is the computation of the resistance encountered by a fish when it passes through an orifice, is fundamentally at variance with the usual assumptions, the variance being analogous to that concerning fish resistance in steep channels

The penultimate chapter contains original suggestions for the design of fishpasses. On one hand, an improved form is proposed for the pool-submerged orifice pass, in which the orifice is replaced by a converging tube. Here the author makes one of his interesting excursions into another field of hydraulic engineering, and gives his ideas on some of the important aspects of the problem of turbulence. On the other hand, he indicates how the Denil principle of energy-dissipation may be adapted to the needs of open channels of very variable depth as well as to closed conduits of rectangular cross-section, and as to how the ordinary Denil channels may be combined with these special conduits in the construction of fishpasses with marked headwater fluctuations. Most of the original and clearly well considered suggestions given in this rather long chapter have not yet been put to the practical test; some of them have not yet been studied under laboratory conditions.

---

* A preliminary experimental contribution to this detailed study by the reviewer and Dr. C. M. White, of the Imperial College of Science, has led to results decidedly in favour of Denil's formula. A joint publication is being prepared for the *Journal of the Institution of Civil Engineers, London.*

The final chapter deals with the unscientific use, or rather abuse, of the Denil principle of energy-dissipation and with the total failures which naturally result from this cause.

To sum up the contents of this book, the author contributes to the following distinct, though overlapping fields of work: (1) fish biology (mainly mechanics, physiology and psychology of fish migration); (2) practical fish protection (mainly fishpass design); (3) hydraulic engineering in general; (4) fluid mechanics.

I consider Denil's contributions of the greatest importance to fishpass design and to hydraulic engineering in general, and this mainly because of the great value of the Denil principle of energy-dissipation for the economy of fishpasses and probably of some other hydraulic structures such as timber-floating channels, spillways, ship canals and perhaps surge tanks as well. Because of the value—partly actual, partly potential—of the author's fishpass designs, it is regrettable that many of his illustrations regarding these designs are difficult to understand. A few are quite unintelligible or are ambiguous. It is to be hoped that an English translation, which will be awaited anxiously by investigators in widely different fields, will not only be devoid of this minor and disconcerting fault, but will also provide more of the wealth of material from laboratory experiments and velocity measurements for actual fishpasses which Denil has made during his exceptionally thorough investigations.

Even so, the present book, valuable as it is for the number of well-supported experimental results it contains, will be still more valuable for its suggestions of problems to be followed by independent investigators in different fields of work. In particular, research in the field of fluid mechanics will have to concern itself with two important problems raised in Denil's book. These are the deeper physical cause of the extremely efficient energy dissipation given by the Denil system, and the resistance problem of swimming bodies in channels of very varied type.

PAUL NEMENYI.

THE CULTURAL HISTORY OF MANKIND

A History of World Civilization
By Prof. James Edgar-Swain. Pp. xix+615. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 15s.

IN six hundred and fifteen pages the author of this book surveys the whole cultural history of mankind, tracing the development of politics, art, religion, science, literature, economics and social life through the ages. Broadly speaking, his classification of topics under periods is—prehistoric and early empires, classical civilization, taking in, in addition to Greece and Rome, early India, China and Central and South America, the Middle Ages, the development of national cultures, and subsequent history down to the close of the War of 1914-18 and "Beginning of an International Culture". In the survey of each section the story of the course of events under each topic is followed by an evaluation of the contribution of the period or people under review to progress.

It is very doubtful whether a survey of this ambitious scope, even of the most elementary character, can be undertaken at the present time by any but a syndicate of experts. Prof. Swain is not unconscious of the difficulty; but his equipment for the task he has so boldly undertaken is open to question. Much of his work reads like notes for lectures to students, who may be expected or required to supplement them by more extended study. For the reading public the treatment is too factual and, notwithstanding the evaluating summaries, too little concerned with the broader aspects of trends and movements in development. This, however, is a matter of method and treatment on which opinion may differ; but in other respects, the book shows serious defects. Apart from errors of fact, which are too numerous, statements are made which, when not categorically erroneous, are gravely misleading.

These defects are especially apparent in the early sections of the book, which deal with prehistory and protohistory down to the close of the 'classical' section. The table of prehistoric civilizations is ludicrously inadequate, as well as inaccurate, omitting mesolithic entirely; while owing to the treatment of protohistoric civilizations—"ancient empires"—in water-tight compartments on a topographical basis, the whole implication of modern research is missed.

The author would appear here to have used sources which either are out of date and now need supplement and correction, or to have no first-hand acquaintance with the material. He is twelve or fourteen years behind current knowledge. The important archæological discoveries of the prehistoric civilizations of India and China, and the later work in Sumeria of Sir Leonard Woolley (whose name is misspelled), with their influence on outlook and study of the development of the respective cultures are ignored. In another field the same neglect of recent development is shown when in the account of the British constitution the term 'colonies' is still used, and the constitutional relations of Britain and other constituent members of the British Commonwealth of Nations are described in terms which ceased to be applicable after the passing of the Statute of Westminster.

Prof. Swain does not seem invariably to be too well acquainted with the authorities he cites. He refers to the single volume edition of "The Golden Bough" as entitled "Leaves from the Golden Bough" and as "selected by Mrs. Frazer".

THEORIES OF HEARING

Hearing

Its Psychology and Physiology. By Dr. Stanley Smith Stevens and Dr. Hallowell Davis. Pp. xv+489. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1938.) 22*s*. 6*d*. net.

IN spite of all the work which has been done on the ear, it is common knowledge that we still do not know precisely how the ear works. When Weaver and Bray first announced their discovery of the electrical potentials produced by the ear, it looked as if the resonance theory of Helmholtz would have to be finally abandoned. It was found, however, that an incorrect interpretation had been placed on these researches, so that to-day there are probably more believers in the resonance theory than ever before.

It is particularly interesting, therefore, to read this book by Stevens and Davis, since they do not believe in the resonance theory, but in a travelling bulge theory. Now there is nothing particularly new in travelling bulge theories, for they have been proposed from time to time by several experimenters. The evidence put forward by Stevens and Davis is the work of Békésy, who made large-scale physical models, measured the velocity of transmission of the bulge in them, and applied the data thus obtained to the human ear. He also did experiments in which a click and a steady tone are presented simultaneously to the ear.

Now, so far as evidence of models is concerned, a large number have been made. Some of them demonstrated strictly localized vibrations, such as one would expect to find according to the resonance theory of hearing; others, such as those made by Ewald, showed the development of a number of affected regions for single pure tones, thus suggesting the sound pattern theory. Békésy's models, on the other hand, demonstrated a travelling bulge. It seems to me that until we know more about the physical properties of the cochlea, and the physical properties of these models, we are really not justified in drawing any conclusion from them at all, except that the makers of the models are extremely ingenious. With regard to the evidence provided by the click and steady tone presented simultaneously, the experiments should be repeated and varied in different ways before they can be held to refute categorically any theory.

With regard to the book itself, much may be said in its favour. It states in a precise but easily understood way a large number of the facts which are at present known concerning the ear. Specially good are Chapters vii and viii on combination tones, masking, etc. Practically all the figures are well illustrated, the only unsatisfactory ones being such photomicrographs as Figs. 113, 132 and 134. Fig. 113 is particularly misleading. It shows Reissner's membrane very bent, the tectorial membrane displaced upwards away from the hair cells, and the basilar membrane seriously kinked with distorted arches of Corti attached to it. Now that histological technique can produce sections of the cochlea which show none of these defects, one of these sections should be used as a basis for this illustration in future editions of this book. This is a matter of detail only. The book as a whole is excellent and is strongly recommended to all those whose interests lie in the border line between physiology and physics.

H. HARTRIDGE

INTERPRETATION OF PLANT STRUCTURE*

BY PROF. D. THODAY
UNIVERSITY COLLEGE, BANGOR

STRUCTURE AND FUNCTION

UNDER the influence of Darwin's concept of 'survival of the fittest', a tendency to assume all structural features to be adaptive was strengthened. It is, of course, essential that the structure of plant organs should enable them to carry out their functions adequately; but perfect adaptation of tissues to their functions would be difficult to define.

The study of xerophytes provides an instructive example.

Before the physiological adaptation of plants to their environments can be properly assessed, we need far more exact knowledge regarding the quantitative relations of their different functions to the environmental factors, and regarding the balancing of those functions.

The question to be answered is not how an organ is adapted to its function, but rather *how its form and structure affect its functioning*.

Quantitative investigation of the effects of minute structural features is often beset with great difficulty. We have not even yet reached finality in the solution of problems presented by stomatal diffusion, as affected by wind and other external conditions and by the size and proximity of the stomatal pores, although much intensive work has advanced our knowledge considerably; nor do we know just how much effect to attribute to the sinking or raising of stomata, or other special devices.

While the exact laws of the diffusion of gases through stomata are difficult to establish, it might be thought that the *distribution* of stomata at least would lend itself readily to adaptational interpretation. Actually, the facts point very largely in the reverse direction. Salisbury's statistical studies in particular have shown that, on the whole, plants in more exposed places have a higher stomatal frequency, and that for a given species the proportion of stomata to epidermal cells is more constant over a range of moisture conditions than stomatal frequency, variations in which are to be interpreted largely as the consequence of different degrees of expansion subsequent to the initiation of the stomata.

This turns the attention away from adaptation to the process of development. Salisbury's results indicate that stomatal frequency is determined by factors at work in two phases of leaf development. The first is the formative phase in which the position and number of stomata are determined in relation to the epidermal cells, mainly by internal influences depending on the hereditary make-up of the plant. The second is the expansion phase, in which the degree of separation of the stomata, already initiated, is determined.

Goebel has shown how problems of development may be attacked inductively in his "Gesetzmässigkeiten im Blattaufbau". The general result of his studies of leaf development was to bring out the repetitive nature of the patterns that are laid down, the units of a pattern showing, at the time of initiation, remarkable constancy of scale. Thus at the growing edge of a fern frond bifurcation of the veins keeps their spacing within certain limits, just as the size of cells in meristems tends to remain more or less constant owing to division when an upper limit is reached. The uniformity of size of the meshes in a net-veined leaf is a similar phenomenon which has been studied by Schuster. Stomata and also root-hair initial-cells show an approximation to uniformity of spacing at their initiation, however much the fact may afterwards be obscured by expansion of cells between the initials, or inhibition of their further development. Küster has emphasized the correlational aspect of such regularities, as depending upon mutual relations between the different tissues or structural elements that make up the pattern.

Another example of a quantitative approach to problems of adaptation is afforded by attempts to correlate the dimensions of parts served and tissues serving them. It is obvious that as the foliage of a tree increases in extent the amount of conducting tissue in the stem increases too; and that from the small twig through branches to the main trunk the amount increases parallel with the increasing number of leaves to be supplied. Jaccard directed attention to the quantitative aspect of this relation; and his pupil Rübel examined it in greater detail for the herbaceous plant, *Helianthus annuus*. Salisbury had already correlated the vascular structure of petioles with the dimensions of the leaf blades, with special reference to the xylem and transpiration.

The correlations displayed were not exact and showed considerable variations. Yet they are remarkable enough, and specially worthy of note when we begin to inquire how such correlations come about. An interaction between one part and another is implied. This aspect has been investigated both experimentally and by anatomical analysis.

---

* From the presidential address to Section K (Botany) of the British Association, delivered at Dundee on September 1.

Jost's classical experiments on Phaseolus seedlings (1893) showed that severance of leaf-trace bundles in the middle of an internode interrupted their development below the point of severance, but not above it, although neither part could function normally.

In herbaceous plants, cambial activity at any given level often exhibits local variations which are related to active development of different leaves above. In the sunflower this is conspicuously shown.

That the developing organs actually influence the growth of the stem below them, to considerable distances, is a natural inference.

Strong support for the reality of such influences has been forthcoming from one of the most spectacular advances in knowledge in recent years—the discovery of chemical agents controlling growth, which was an outcome of investigations on the curvature of shoots in response to light. The growth-promoting substances, called auxins, are highly active. One fifty-millionth of a milligram produces a measurable effect on the oat coleoptile. They are produced especially by actively growing parts of shoots—sprouting buds, shoot-tips and young expanding leaves. They not only influence growth in length, but also produce other effects which are of greater interest in the present connexion.

It has been shown experimentally by Snow and confirmed by others that auxin stimulates cambial activity. Söding has actually detected auxin in the cambium of trees in spring and summer. He states that it appears there a little in advance of the resumption of cambial activity in the spring. Since it is produced by developing buds and young leaves and travels downwards, the downward spread of cambial activity from the base of the awakening buds in spring is thus accounted for in terms of an effect of auxin which is experimentally demonstrable. The basipetal conduction combined with tangential localization exhibited in this instance gives strong support to the interpretation, already suggested, of the localized cambial activity in the intact sunflower stem, as indicating a causal influence proceeding downwards from the actively growing leaves.

Evidence has also been adduced of stimulating agents of a chemical nature liberated from wounded tissues.

The demonstration that such hormones exist and are effective in influencing plant development is of far-reaching significance. It is a challenge to students of plant structure to view their data dynamically. The statement that one part of a plant influences another is no longer to be understood merely as a convenient way of expressing a correlation, in a figurative sense, but is a legitimate hypothesis in a causal sense.

THE PHYLETIC OUTLOOK

The evolution theory gave a new meaning to natural relationships, as revealed by the systematist, and a new aim to the systematist himself. Previously a natural system was conceived as a system of classification depending on the balance of similarities, estimated from a consideration of all the characters of the species, as compared with an artificial system depending on particular characters selected for their convenience. The ancestry of species now became, in theory, the main basis for a natural classification.

It was soon realized that, as similarities in some features are often accompanied by dissimilarities in others, similarity might not always signify relationship. Fossils themselves, moreover, provided clear evidence that similar organs or structures have been evolved independently along different lines, by different phyla, so that the possession of seeds, for example, is not evidence of common ancestry for all seed-bearing plants.

Modern genetics reveals, as the most prolific cause of variation, irregularities in the process of nuclear division and the behaviour of the chromosomes, and changes in the substance or structure of the chromosomes, which appear to be entirely erratic and haphazard.

If, however, we turn from the minor variations which differentiate species and horticultural varieties and survey the major events that have marked the evolution of plants, it is difficult to regard these as haphazard. Besides seeds, already mentioned, a number of features are found with even wider distribution, common to groups which cannot be traced to a common origin. Such are the alternation of sexual and asexual generations; archegonia; the formation of spores in tetrads, following a reduction division; air-space systems and stomata; vascular tissues; then fertilization, evolved also in the animal kingdom, and the cell as the unit of construction; the nucleus with its chromosomes and their highly organized behaviour in division. The enumeration need not come to an end on the plane of cellular, structural organization, for chemical parallels are quite as remarkable. Consider, for example, the similar enzymes and enzyme complexes responsible for carbohydrate metabolism in yeast, in the higher plant and in animal muscle; the hæmins found in plant and animal cells alike, and the related substances, chlorophyll in the green plant and hæmoglobin in animal blood, with uniquely important functions. Finally, there are the proteins and other important basal constituents of living matter.

The idea was suggested by F. F. Blackman in 1921, in reference to Nef's work on the interchangeability of carbohydrates, that the biologically important carbohydrates are just those which are chemically most likely to arise—most readily formed, most stable, etc. May we not extend this idea to explain the universality of particular chemical compounds or radicals—like the amino-acids, limited in number, found in protoplasm ?

The conditions for an epoch-making event like the arrival of chlorophyll were provided by the previous course of chemical evolution, in common characters of living matter, and by particular variants of them under particular conditions, which may have occurred but rarely in combination, but are scarcely to be envisaged as unique.

If it is legitimate to regard chemical events in this way, as occurring with a frequency concordant with their inherent probability, may we not carry this idea on to the higher plane of cellular organization and structure ? To do so is to direct attention to the nature of that stability and developmental harmony which are so conspicuous a feature of living organisms ; for persistence and occurrence become more and more determined and limited by the pre-existing system through which evolution works. Natural selection of harmonious changes may have been more important than elimination of functionally unfit mature organisms. It is developmental harmony which is important, of which functional efficiency of adult organs is but a part.

We are thus once again led to the consideration of development. If we can obtain light on the laws of harmonious development, we may be in a better position to understand the nature of those major changes which the great pageant of evolution unfolds.

SEEDLING STRUCTURE

As an example of the application of causal principles to old problems, I propose to consider the structure of seedlings.

The broad survey achieved by British workers revealed large differences within closely related groups, which made it more difficult to interpret resemblances as of phylogenetic significance. A high degree of correlation was observed, on one hand, between slender smallness of seedlings and diarch root structure, with two xylem poles extending right up the hypocotyl ; and, on other hand, between large diameter and tetrach or polyarch structure, with stem-like pattern in the hypocotyl. Both Compton and T. G. Hill and de Fraine emphasized seed size as an important factor influencing seedling structure.

Another factor of a similar kind was the influence of the plumule, the traces from which, when precociously developed, shared with the cotyledon traces in the early structure of the hypocotyl. In certain cases, particularly among the Amentiferæ, the traces from the plumular leaves were found to be triads like those from the cotyledons (Davey, 1916), and these with their central xylem strand extend above the cotyledonary node into the epicotylar stem itself. Phylogenists were inclined to interpret this as a more extensive persistence of primitive structure in a relatively primitive group. But the occurrence of a root-like solid core of xylem in the epicotyl of the Viciеæ, an advanced group among the Leguminosæ, scarcely harmonizes with phyletic ideas, as Compton pointed out, and makes phylogenetic interpretations appear less certain.

Bugnon tried to approach the facts objectively, without phyletic aim or preconceptions, from the developmental point of view. As has been recognized since the work of Sanio, the differentiation of the leaf-trace bundles progresses basipetally from the node. Bugnon observed that in *Mercurialis annua*, as in many other plants, they normally fork into two, so avoiding incoming bundles immediately below, before uniting with other bundles lower down. The cotyledon traces likewise fork, though they do this sooner and in relation to the vascular system of the root.

Turning to the radicle, Bugnon notes that the root structure is quite typical. All other roots, however, arise from organs already differentiated. They form their own characteristic pattern of vascular arrangement, and this is linked by commissural elements to the appropriate tissues already present in the parent organ. In the case of the radicle, an exactly similar root apparatus has to be linked up, not with tissues fully differentiated, but with tissues still in a meristematic condition. The connecting tissues are therefore similar to ordinary conducting strands, not special commissural elements.

Bugnon did not, so far as I am aware, attempt to extend the same principles of interpretation to the wider range of facts which have been brought to light, and it appears worth while to see how far this can be done.

In the first place, from a causal point of view, certain principles may be regarded as established. The first is the power of self-determination inherent in growing organs and especially in apical growing points—each developing a characteristic pattern of external form and internal structure. The second is the influence of apical developing organs on the structure of other parts still capable of growth—this applying particularly in the basipetal direction and therefore mainly to the influence of the shoot apex and young leaves on the parts below them.

With regard to the root, a spectacular demonstration of its power of self-determination has been provided by Philip R. White who, following on the pioneer work of Robbins and Maneval, succeeded in 1934 in proving that root-tips cut from the plant can be grown continuously for years in a nutrient solution containing the essential salts, sugar, and a small concentration of an extract of yeast.

In the large adventitious roots of many Monocotyledons, it is particularly evident that no relation exists between the pattern laid down in the root primordium and that already present in the stem to which it has to be connected. The repetitive nature of the pattern and its inherent stability also become more obvious. The alternation of exarch xylem strands with phloem strands, in a ribbon with definite radial polarity, expresses a harmonious balance of influences and developmental processes. The fundamental uniformity of the root pattern throughout the great majority of vascular plants is further evidence of this inherent stability.

To turn to the shoot: it will probably be admitted that the shoot apex is a self-determining and dominant centre of development. It controls the polarity of the shoot, and round it the repetitive pattern of leaf primordia unfolds. The apical bud as a whole controls also primary development and secondary growth in the stem below. There is much in the system of relations exhibited which is reminiscent of the part played by organizers in the development of animal embryos.

In the determination of primary structure in the stem the leaf primordia play a predominant part. The number of vascular strands in the leaf base depends partly on hereditary factors, but partly on size. This is particularly clear in Monocotyledons, where the bundles arise in succession, separated by parenchyma, as the new leaf primordium extends round the apex.

Now, in seedlings the conditions are unique. At two ends of a short meristematic axis are two self-determining centres of different kinds in close proximity, two opposite poles, a shoot pole and a root pole, each of which is capable of impressing its own inherent pattern on the meristematic tissues to which it gives rise. Under these conditions we cannot assume that the spheres of influence of each will be sharply defined, or that they will necessarily be fixed. If the influence of the poles depends on hormones emanating from them, the boundary might well change with changes in relative vigour of the two organizing centres, and differ also from one species to another.

It appears reasonable, therefore, as a working hypothesis to interpret the structure of seedlings in the following way:

(1) The cotyledons and, if the plumule is precocious, the plumular primordia, influence the number of procambial strands in the hypocotyl and its diameter growth at an early formative stage. The form of the cotyledons plays a part. Nutritive and other factors afterwards affect the expansion of the hypocotyl and the degree of separation of the bundles by parenchyma.

(2) Differentiation within the strands of procambium is controlled initially by the root apex in the majority of cases, but to a variable distance upwards. The triad represents the smallest unit of the root pattern, existing as a detached arc, whether in the hypocotyl or a dorsiventral cotyledon.

(3) In the upper part of the seedling, sometimes only in the blade of the cotyledon, sometimes also in the petiole, or even lower, the shoot itself holds sway, and in place of a triad is found a single bundle. The intervening region is one of compromise and accommodation between the two patterns.

(4) With increasing activity of the shoot, further development is stimulated, from above downward, in the formation of centrifugal xylem on the inside of the phloem strands. These appear to be the main channels of the basipetal influence. In Dicotyledons the centrifugal xylem is commonly if not generally the result of cambial activity, which ultimately extends down into the root itself.

One factor in the determination of the relative preponderance of root and shoot is very probably the production of auxin by cotyledons and plumule.

We have seen how a substance of known composition, auxin, acts as an agent in the co-ordination of different parts of a plant, but this does not mean that we can explain the activities that are co-ordinated. Great as have been the advances in biochemistry, we are not yet furnished with the means of expressing in physico-chemical terms the delicacy and subtlety of the adjustments exhibited even in plants.

Take, for example, the adhesive disk and haustorium of a mistletoe seedling. This remarkable organ is the result of a series of co-ordinated responses in the growth of the little green meristematic knob from which it arises. Contact pressure leads to one-sided growth, by which it brings itself face downward on to the surface, to which it adheres with the aid of a special viscous material. There follows further growth of its now dome-shaped outer shell, the edge of which moves slowly outwards as the area of attachment widens. Under the dome, cells of the lower surface grow out as papillæ, which adhere closely to the epidermis or cork of the host twig. By the outward and upward movement of the growing shell and a contraction of tissue within it, the papillæ are lifted sideways and the adhering outer protective layer is torn up. Then new papillæ fasten themselves to the next cork layer and the tearing process is repeated. In this way several such layers may be picked up until a breach is made in the periderm, giving access to the living tissues within. Through this slit the wedge-shaped haustorium grows.

It is strikingly obvious in a specialized organ such as this, where growth is closely and uniquely adjusted in response to a particular environment and in relation to a peculiar, special mode of life, that structure and behaviour are interdependent. There is, however, no logical justification for neglecting to interpret the development of ordinary plant organs on similar lines. The main difference is that the cells respond chiefly to internal influences, though the organ as a whole exhibits tropic curvatures in response to appropriate external stimuli.

It is not possible to pursue this line of thought further; but reference should be made to the work that has already been done by Schüepp, Priestley, Adriance Foster, Helm, Grégoire, Snow, the veteran Schoute, and many others towards the elucidation in detail of the course of differentiation in the shoot of Dicotyledons and Monocotyledons, from which are gradually emerging a better understanding of the principles of their developmental organization.

NUCLEAR REACTIONS IN STELLAR EVOLUTION

By Prof. G. Gamow,

George Washington University, Washington, D.C.

(1). THE question of the sources of energy of stars, and the closely connected question of stellar evolution, have presented for a long time the most important unsolved problem of theoretical astrophysics. The first step towards the understanding of the physical processes leading to the tremendous energy liberation which is responsible for the observed radiation of stars was made about ten years ago. It was shown[1], on the basis of the quantum theory of nuclear transformations, that, at the very high temperatures existing in the interior of stars, the ordinary thermal collisions between the particles possess sufficient energy to produce artificial nuclear transformations. It was also shown that the energy liberation in such *thermo-nuclear reactions* is sufficiently high to explain the radiation of stars only in the case of collisions between the protons and the nuclei of light elements (up to about atomic number 10). It took, however, ten more years before our knowledge concerning nuclear reactions developed to such an extent that it became possible to choose particular nuclear reactions as responsible for the energy-production in different cases and to give on this basis a clear and consistent picture of stellar evolution. The exact formula for the energy production of a thermo-nuclear reaction (per gram per second) can be written in the form[2]:

$$\varepsilon = \frac{4}{3^{5/2}} \rho X_1 X_2 \frac{\hbar \Gamma r_0^2 Q}{m_1 m_2 m e^2 Z_1 Z_2} \exp.\left(\frac{2v_0 m e^2 Z_1 Z_2}{\hbar^2}\right)^{1/2} . \tau^2 e^{-\tau} \qquad (1)$$

Here ρ is the density of the gas, X_1 and X_2 the concentrations (by weight) of the two reacting types of nuclei, m_1 and m_2 their masses ($m = m_1 m_2/(m_1 + m_2)$), $Z_1 e$ and $Z_2 e$ their electric charges, r_0 the combined radius, Q the energy production per reaction, and $\Gamma/\hbar$ the probability of reaction after the penetration through the potential barrier. The dependence upon temperature is given through τ, which is defined by:

$$\tau = 3\left(\frac{\pi^2 m e^4 Z_1^2 Z_2^2}{2\hbar^2 kT}\right)^{1/3}, \quad . \quad . \quad . \quad (2)$$

T being the absolute temperature of the gas and k the Boltzmann constant.

This formula was used[3] in choosing the nuclear reaction responsible for the energy liberation of the sun. The complete list of all possible reactions between the protons and different light nuclei is given in the accompanying table, together with the values of Q and Γ:

Reaction	Q (mMU)	Γ (ev.)	$\varepsilon\left(\frac{\text{erg.}}{\text{gm. sec.}}\right)$
$^1H + {}^1H \rightarrow {}^2H + e^+$	1.53	Ref. 4	2.2
$^2H + {}^1H \rightarrow {}^3He + h\nu$	5.9	1	$1 \times 10^{+17}$
$^3H + {}^1H \rightarrow {}^4He + h\nu$	21.3	10	$3 \times 10^{+16}$
$^6Li + {}^1H \rightarrow {}^4He + {}^3He$	4.1	5×10^6	$1 \times 10^{+16}$
$^7Li + {}^1H \rightarrow 2\,{}^4He$	18.6	4×10^4	$5 \times 10^{+15}$
$^9Be + {}^1H \rightarrow {}^6Li + {}^4He$	2.4	10^6	$3 \times 10^{+10}$
$^{10}B + {}^1H \rightarrow {}^{11}C + h\nu$	9.2	10	$3 \times 10^{+6}$
$^{11}B + {}^1H \rightarrow 3\,{}^4He$	9.4	10^6	$2 \times 10^{+11}$
$^{11}C + {}^1H \rightarrow {}^{12}N + h\nu$	0.4	0.02	1.1
$^{12}C + {}^1H \rightarrow {}^{13}N + h\nu$	2.0	0.6	180
$^{13}C + {}^1H \rightarrow {}^{14}N + h\nu$	8.2	30	$3.6 \times 10^{+4}$
$^{14}N + {}^1H \rightarrow {}^{15}O + h\nu$	7.8	5	30
$^{15}N + {}^1H \rightarrow {}^{12}C + {}^4He$	5.2	10^6	$4.5 \times 10^{+2}$
$^{16}O + {}^1H \rightarrow {}^{17}F + h\nu$	0.5	0.02	7×10^{-2}
$^{19}F + {}^1H \rightarrow {}^{16}O + {}^4He$	8.8	10^6	55
$^{20}Ne + {}^1H \rightarrow {}^{21}Na + h\nu$	10.7	10	7×10^{-3}
$^{24}Mg + {}^1H \rightarrow {}^{25}Al + h\nu$	8.0	10	8×10^{-6}
$^{28}Si + {}^1H \rightarrow {}^{29}P + h\nu$	7.0	10	3×10^{-22}

The last column gives the calculated energy liberation of different reactions for the conditions existing in the interior of the sun (that is, $T = 2 \times 10^{7}$° C.; $\rho = 80$ gm./cm.^{3} and $x_{\text{hydrogen}} = 0{\cdot}35$) with the additional hypothesis that the concentration of the element in question is 0·1 (except, of course, the first reaction, where both X_1 and X_2 are taken to be 0·35).

The observed average energy production of the sun is 2 ergs/gm.sec., which corresponds to an energy production of about 60 ergs/gm.sec. in the central regions. Comparing this value with the numbers in the last column of the table, we see at once that the nuclei ^{2}H, ^{3}H, ^{6}Li, ^{7}Li, ^{9}B, ^{10}B and ^{11}B, if present at all, should have extremely small abundances in the central regions of the sun; otherwise the rate of energy production would exceed the observed radiation of the sun by a factor of several millions. Thus these reactions can scarcely be responsible for the solar energy, because, due to the exceedingly small abundances of the elements in question, the total energy produced would not suffice to explain the long life of the sun required by geological data.

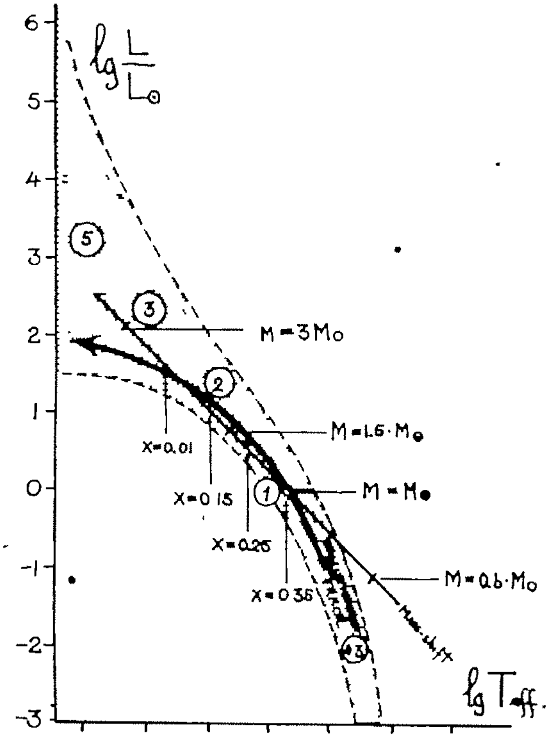

FIG. 1.

On the other hand, the oxygen and all heavier elements (with the possible exception of fluorine, which is present, however, only in minute amounts) cannot give sufficiently high energy production at solar temperatures.

Moreover, the exact calculations show that β-emitting reaction between two protons also leads to an energy liberation which is about thirty times too low for the sun.

The remaining reactions, of carbon and nitrogen nuclei, seem to be therefore the only possibility. It should be noticed first of all that these reactions possess a very important property, forming a *cyclical* chain in which both elements are permanently regenerated. We have in fact the following sequence:

$$\begin{aligned}
{}^{12}\mathrm{C} + {}^{1}\mathrm{H} &\rightarrow {}^{13}\mathrm{N} + h\nu \\
{}^{13}\mathrm{N} &\rightarrow {}^{13}\mathrm{C} + e^{+} \\
{}^{13}\mathrm{C} + {}^{1}\mathrm{H} &\rightarrow {}^{14}\mathrm{N} + h\nu \\
{}^{14}\mathrm{N} + {}^{1}\mathrm{H} &\rightarrow {}^{15}\mathrm{O} + h\nu \\
{}^{15}\mathrm{O} &\rightarrow {}^{15}\mathrm{N} + e^{+} \\
{}^{15}\mathrm{N} + {}^{1}\mathrm{H} &\rightarrow {}^{12}\mathrm{C} + {}^{4}\mathrm{He}
\end{aligned} \tag{3}$$

We see that in this chain both ^{12}C *and* ^{14}N *nuclei play only the rôle of catalysts and that the final result of the cycles is the transmutation of hydrogen into helium.*

The rate of the reaction chain is always determined by the rate of its slowest link which is, in our case, the proton capture by ^{14}N. With this rate and the energy liberation of 4×10^{-5} ergs per cycle, one obtains for the rate of energy production the value 100 ergs/gm. sec., in excellent agreement with the actual value.

Thus there seems to be no doubt that *energy production in the sun is due to the carbon-nitrogen reaction cycles*[3].

(2). We can now answer the question concerning the characteristics of stars with the same energy-producing reaction but different masses and chemical constitution, by comparing them with the sun by means of the so-called *homology transformations* of stellar models. There are *nine* different physical quantities defining the external properties and internal structure of a star: the total mass M, the total luminosity L, the radius R (or the effective temperature defined by $T_{\text{eff.}} = \sqrt[4]{\frac{L}{4\pi R^2 \sigma}}$), the average molecular weight μ, the coefficient of opacity of stellar matter $\varkappa_e$, the product of concentrations of two kinds of reacting nuclei X_1X_2 and the functions of ρ, p and T giving the distribution of density, pressure and temperature in the stellar interior. These quantities are connected by *five* fundamental equations: the definition of mass M through ρ and R; the equation of hydrodynamical equilibrium; the gas law; Eddington's equation for the transport of energy; and the formula giving the rate of thermo-nuclear energy production. Thus, choosing for four independent variables the M, μ, $\varkappa_e$ and X_1X_2, we can determine the relative changes of other variables by simple proportionality relations.

It is customary to classify the stars in the frame of the so-called Hertzsprung–Russell diagram, plotting the logarithms of absolute luminosities against the negative logarithms of effective temperatures.

For these two directly observable quantities we have the following homology transformations[3]:

$$\left(\frac{L^1}{L}\right) = \left(\frac{M^1}{M}\right)^{\frac{4n+13\cdot25}{n+1\cdot75}} \left(\frac{\mu^1}{\mu}\right)^{\frac{5\cdot5n+20\cdot25}{n+1\cdot75}} \left(\frac{\varkappa_0^1}{\varkappa_0}\right)^{-\frac{n+3}{n+1\cdot75}}$$

$$\left(\frac{X_1^1X_2^1}{X_1X_2}\right)^{-\frac{1\cdot25}{n+1\cdot75}} \qquad (4ab)$$

$$\left(\frac{T_{\text{eff}}^1}{T_{\text{eff}}} =\right)\left(\frac{M}{M}\right)^{\frac{10\cdot5n+4\cdot94}{n+1\cdot75}} \left(\frac{\mu^1}{\mu}\right)^{\frac{0\cdot87n+9}{n+1\cdot75}} \left(\frac{\varkappa_0^1}{\varkappa_0}\right)^{-\frac{0\cdot25n+1\cdot25}{n+1\cdot75}}$$

$$\left(\frac{X_1^1X_2^1}{X_1X_2}\right)^{-\frac{0\cdot81}{n+1\cdot75}},$$

where n is the exponent in the temperature dependence of N–C-cycles, which at temperatures around 2×10^{7}° C. is equal to 18.

If we consider stars with the same chemical constitution, the values of L and $T_{\text{eff.}}$ will depend only on M, and this dependence is shown by a straight line in Fig. 1, representing the above-mentioned Hertzsprung–Russell diagram. The numbers along the line correspond to the values of $M/M\odot$. The shaded area represents the so-called *main sequence* in which most of the known stars are located, and the observed masses of stars are indicated by numbers in little circles. The close agreement between the observed and calculated locations brings us to the conclusion that *the main sequence should be interpreted as the collection of stars of different masses with the same chemical constitution and the same energy-producing reaction as in the sun (that is, C–N-cycles).*

Although the agreement between the observed values of M, L and the theoretical relations (4ab) with $n = 18$ is excellent for the stellar masses between 0·5 $M\odot$ and 2·0 $M\odot$[4], there are quite noticeable deviations at both ends of the main sequence. The deviations for very luminous stars of large mass are, most probably, due to the effect of the high radiative pressure, which has to be neglected in the derivation of the homology transformations. On the other hand, the deviations at small luminosities might be due to the fact that for these stars the C–N-cycle is no longer the main energy-producing reaction. We have seen above that in the sun the ^{1}H + ^{1}H reactions give only 1/30 of the total energy production; however, due to its comparatively small temperature dependence, this reaction becomes predominant at temperatures below $1\cdot5 \times 10^{7}$° C., which just correspond to central temperatures of stars on the lower part of the main sequence.

We can now apply the homology transformations (4ab) to the study of evolutionary changes of a star due to the continuous consumption of the hydrogen supply by the energy-producing reaction. The transmutation of hydrogen into helium increases the average molecular weight μ and the opacity $\varkappa_0$ of the stellar substance and decreases the value of X_1X_2 (in which X_1 is now the constant nitrogen content, and X_2 the variable hydrogen content). This defines the changes of the luminosity and the effective temperature and enables one to draw the evolutionary track of the star in the Hertzsprung-Russell diagram. In Fig. 1 such a track for the sun is shown by the heavy line, the numbers along the track representing the hydrogen content at different stages of the evolution. We see that *during the process of the (hydrogen-) evolution the luminosity and the effective temperature of any star, and in particular of our sun, is bound to increase by quite a considerable amount.* But inasmuch as for the sun it would take $1\cdot2 \times 10^{11}$ years to burn all its present hydrogen content, the yearly changes of the luminosity and spectral class are quite negligible and could not be detected by observation.

Here, however, is an important question. If different stars at different stages of their evolution possess quite different luminosities, there should be no correlation between the luminosities and masses of stars; this is, however, in contradiction with the well-established existence of the empirical mass-luminosity relation. The solution of this difficulty is very simple[7]. The rate of consumption of hydrogen at different stages of the evolution is evidently proportional to the total luminosity of the star. Thus the star will stay a much longer time in the lower part of its evolutionary track and pass much more quickly through the stages of high luminosity. *Thus the empirical mass-luminosity relation should be considered as a statistical regularity due to the fact that most of the stars are observed in the lower part of their evolutionary track.* A more detailed survey of stellar masses must necessarily lead to the detection of stars with luminosities considerably higher than those required by the ordinary mass-luminosity relation. It should be noticed, however, that for the stars in the lower half of the main sequence, such late stages of the hydrogen evolution probably could not be observed at all, because the evolutionary life of these stars is considerably longer than the period of time ($\sim 10^{9}$ years) which has passed since their formation.

OBITUARIES

Dr. A. C. D. Crommelin

We deeply regret to record the death of Dr. A. C. D. Crommelin which occurred on September 20. Andrew Claude de la Cherois Crommelin was born at Cushenden, Co. Antrim, on February 6, 1865, being the third son of Mr. Nicholas de la Cherois Crommelin, a member of the Huguenot family of that name. Educated at Marlborough College, he afterwards went to Trinity College, Cambridge, where he graduated as twenty-seventh wrangler in the Mathematical Tripos of 1886.

After leaving Cambridge, Crommelin became for a time an assistant master at Lancing College; but his interests lay in astronomy, and it was fortunate for him that in 1891 the appointment of an additional assistant at the Royal Observatory, Greenwich, was sanctioned. Crommelin proved to be the successful candidate and he joined the staff on May 11, 1891. He was given charge of the altazimuth telescope and of the reduction of the observations of the moon which were made with it. He also undertook the reduction of observations of occultations of stars by the moon and of visual observations of the positions of comets made with the Sheepshanks equatorial. This work he continued to do throughout his career at Greenwich, though the programme of work with the altazimuth telescope became more extensive when, a few years after his appointment, the older instrument of Airy was replaced by a larger and more elaborate one.

The character of his work prompted Crommelin to take up the computation of orbits and ephemerides, and his name soon became known as the computer of the orbits of newly discovered comets and minor planets and of ephemerides for them. But his most important contribution to astronomy was the work he did, in collaboration with Cowell, in investigating the motion of Halley's comet and predicting its position on its return in 1910. Their prediction of the date of perihelion passage differed but three days from that actually observed. This research gained for its authors the Lindemann prize offered by the Astronomische Gesellschaft, and the University of Oxford conferred on them the honorary degree of D.Sc.

Crommelin contributed a number of papers of a similar nature to the *Monthly Notices of the Royal Astronomical Society*, and for more than forty years wrote the annual notes on minor planets and comets, a piece of work demanding much care and research on his part. For some years he computed and published ephemerides for the physical observation of Mars, Jupiter, Saturn and the moon, until this work was undertaken by the "Nautical Almanac". In his private capacity he went on several eclipse expeditions, and in 1919 he was chosen to go on the official expedition to Brazil when the results obtained verified the predicted deflection of light by the sun's gravitational field. For very many years he was a valued contributor to NATURE of notes and articles on astronomical subjects.

Crommelin was elected a fellow of the Royal Astronomical Society in 1888. He served as one of its secretaries from 1917 until 1923 and was president during 1929–31. He was president of the British Astronomical Association in 1904–6 and was for many years director of the Comet Section.

Crommelin retired from the Royal Observatory in May 1927, after thirty-six years service, but he continued to be actively interested in the work of his choice. He married, in 1897, Letitia, daughter of the Rev. Robert Noble. Mrs. Crommelin died in 1921, and he lost his elder son and younger daughter in tragic circumstances. He is survived by one son and one daughter.

Commander F. Wild, C.B.E.

COMMANDER FRANK WILD, whose death took place on August 21, was born at Skelton, in Yorkshire, in 1873. His father was clerk of the Eversholt Parochial Charity at Woburn (Beds.) and on his mother's side he claimed descent from the celebrated antarctic pioneer, Captain Cook. He entered the Merchant Service in 1889, receiving his early training in sail in the famous clipper ship *Sobraon*. He entered the Royal Navy in 1900, and was serving as an A.B. in the *Vernon* when he was appointed to the National Antarctic Expedition (1901–4) under Scott. On this expedition, while still serving as a naval rating, he earned the praise and admiration of Scott himself for his coolness and resource under danger and for his qualities of leadership. But even more important for his future career was the attachment which grew up then between him and Shackleton, an attachment which developed into a lifelong friendship.

Wild's subsequent polar career is well known. He returned to the Antarctic with Shackleton in the *Nimrod* in 1907 "in charge of provisions", and took part, along with Shackleton, Adams and Marshall, in that magnificent journey which all but reached the Pole. Almost immediately afterwards he joined the Australasian Antarctic Expedition of 1911–14 under Dr. Douglas Mawson, during which he commanded the Western Base on Queen Mary Land. At the conclusion of this expedition, after a brief interval ashore, he sailed again with Shackleton on the eve of the War of 1914-18 in the ill-fated *Endurance*. After the loss of that vessel in the Weddell Sea, he remained in charge of the expedition on Elephant Island, and there through four and a half months of extreme privation he pulled through to health and safety twenty-one semi-starved and ill-clad men.

After the tragic death of Shackleton at South Georgia in 1922, Wild commanded the Shackleton-Rowett Antarctic Expedition of 1921–22 in the *Quest*. Although the vessel failed to reach her main objective, the Enderby-Coats Land coast, useful work was accomplished, covering a wide scientific field, notably on the islands of South Georgia, Elephant, Gough, Tristan da Cunha and others.

During the War of 1914–18, Wild led a commercial expedition to Spitsbergen and served in the R.N.V.R. with the rank of Commander. He went to South Africa in 1922 and engaged in farming. The venture failed, and, like so many others who have served a great cause with selfless devotion, he fell upon hard times. He was granted a Civil List pension shortly before his death.

Wild was a little man of slight build. Most indeed would have called him frail until they felt the power of his hands or saw him trimming coal in the intense heat of a ship's bunker in the tropics, or swinging back on a topsail halyard. He had bright, piercing blue eyes which twinkled at you when he spoke. They twinkled most—with sheer pleasure—during the headlong rush and excitement of shortening sail in heavy weather, or when, as he often did, he held the steer-oar of a small boat while negotiating a dangerous landing on a lee shore.

Wild was essentially a seaman of high quality, and a leader of men. His scientific achievement can therefore only be fairly judged by the work of those specialists—the surveyors, geologists, meteorologists, zoologists and others—who were placed in his charge and were encouraged by his example. It is perhaps not generally realized, however, that it was Wild who discovered the coal seams in the great Beacon Sandstone formation high up on the Beardmore Glacier in 85° S. His detailed description of these coal measures is incorporated in the publications of the late Sir T. W. Edgeworth David.

As leader of Mawson's Western Party he was responsible for a notable contribution to antarctic exploration and research when he opened up Queen Mary Land by sledge under conditions which have seldom, if ever, been equalled for severity in the history of polar research.

If there was work to do, however hard or unpleasant the task, Wild never spared himself. His devotion to the cause which he served, his unquenchable spirit under severe trial, his cool head in emergency, his complete selflessness and, above all, his ever ready and kindly advice made him loved and respected by all who served with him throughout his long polar career.

JAMES W. S. MARR.

WE regret to announce the following deaths:

Prof. Sigmund Freud, For. Mem. R.S., formerly professor of neurology in the University of Vienna, on September 23, aged eighty-three years.

Dr. J. A. Loeser, author of "Die psychologische Autonomie des organischen Handelns", in which novel views on animal behaviour were put forward, on September 12, aged forty-one years.

Dr. G. M. Murray, emeritus professor of medicine in the Victoria University of Manchester, known for his work on diseases of the thyroid gland, on September 21.

NEWS AND VIEWS

The British Association in War Time

SINCE the Dundee meeting of the British Association was brought to an untimely end, the office at Burlington House, London, has been re-opened for the routine work which always follows upon the annual meeting, and a certain amount of official business is also being carried on at Down House, where the rooms normally open to the public are closed and dismantled, and Charles Darwin's former dining-room serves the valuable if regrettable purpose of an office-refuge. The first number of the new quarterly report, *The Advancement of Science*, will be produced, all being well, probably rather later than the announced date at the end of October, and in smaller bulk than was contemplated. As to its future, and, for that matter, the future of the Association's work generally, obviously nothing definite can be stated. Preparations for the intended meeting next year in Newcastle-upon-Tyne have been suspended, by agreement with the authorities there. It is an unhappy coincidence that the last meeting in that city was the last to be held during the last war, in 1916. Conditions are so far different now that it is impossible to estimate whether any sort of meeting could or should be held next year, whether in Newcastle or anywhere else. Yet it is permissible to dream of the possibility of adapting the Association's very flexible constitution to a meeting of four days or so, with science in war time as the leading theme, with sessions in three or four telescoped sections—physical, biological, anthropological, and economic, for example—and of course the Division for the Social and Economic Relations of Science. No doubt before anything of this sort could be undertaken there would be need of careful and wide inquiry as to the amount of support which might be forthcoming for such an effort. But if this were favourable, such a meeting could be arranged at relatively short notice. "The minor humours of war" may be offered in advance as one subject on the anthropological side.

The Fourth Partition of Poland

DURING the twenty years of its existence as an independent republic, Poland, like Czechoslovakia, fostered science and learning in a manner which gained the admiration of the whole civilized world. Its President, Prof. Ignacy Mościcki, was a distinguished chemist, and many other men of science took leading roles in the country's affairs and were able to ensure that education, science and culture were not neglected. There were thus very flourishing universities at Warsaw, Cracow, Lwów, Poznań, Vilno and Lublin. Almost every important town had its polytechnic high-school and there were special colleges and institutes connected with agriculture (Warsaw, Pulawy and Bydgoszcz), mining (Cracow) and veterinary science (Lwów), in addition to various scientific academies and societies in different centres.

It is doubtful whether these centres of science will function again before the end of hostilities, and even if some attempt were made to utilize them it will not be for Polish science and culture, since the unhappy nation is again witnessing a partition, the fourth, of the State. From what appears to be the intention of Poland's invaders, Germany will gain possession of the seats of learning at Warsaw (the university is in the western half of the city), Cracow, Bydgoszcz and Poznań, whilst those of Lublin and Lwów will pass into Russian hands. The fate of Vilno and its university and cultural institutes is not certain, since the possibility of its return to Lithuania must not be excluded. Our sympathy goes out to the many men of science in Poland whose work has been interrupted and who have to suffer the horrors of a modern war in which they are the victims of unprovoked aggression.

Patents in War Time

Various Acts of Parliament and statutory rules control the issue of patents. They lay down definite time limits within which certain things must be done by an inventor who is applying for a grant. For example, the complete specification must be filed not later than twelve months after the provisional, and the application as a whole must have reached the stage of being "in order for acceptance" not later than eighteen months after the earliest filing date. In the same way renewal fees must be paid promptly as they fall due, or the patent will lapse. Extensions of time varying from one to three months can be obtained on payment of stipulated fees, but after that no extensions are allowed. In the *Electrical Review* of September 22, a "Legal Correspondent" writes an instructive article on the effects of the new patent legislation. The 'intellectual property' which is created by the operation of the patent system, as well as the artistic property which is called copyright, both stand in a class apart from the ordinary trade and business of mankind. It is therefore for the benefit of all that they should be safeguarded even when they come from an enemy source.

The changes to be made in patent procedure, in order to meet the abnormal conditions of war, are set out in the new Patents, Designs, Copyright and Trade Marks (Emergency) Bill, to which the Royal Assent was given on September 21. The first clause of the Act states that any existing license granted under a patent does not become invalid simply because the proprietor or owner of the patent is an enemy. Clause 4 of the Bill preserves the right of an enemy, even during the period of hostilities, to apply for the grant of a British patent. At the end of the war of 1914–18, the sudden release of patents claiming priority-dates, which in some cases went back for five or six years before the specifications were formally accepted and published, naturally created considerable confusion and embarrassment. When the next armistice comes, we may reasonably expect that the experience gained in similar problems twenty years ago will stand us in good stead.

Food Production in War Time

The Agricultural Research Council is to work in the closest co-operation with the Ministry of Agriculture and the Department of Agriculture for Scotland in connexion with research and investigations into problems that may arise from the food production campaign. Since March last a committee of the Agricultural Research Council has had under examination the programmes of research and the qualifications of the staffs of agricultural research institutes from the point of view of an emergency. It will be the function of the Council now to guide the research at these institutes into the special agricultural problems arising out of war conditions. For this purpose the chairman of the Agricultural Research Council (Sir Thomas Middleton) has, with the approval of the Lord President of the Council, appointed a small executive committee, which will keep all members of the Council in close touch with the situation.

The Minister of Agriculture and Fisheries has also constituted an advisory panel the members of which will be available for consultation, as need arises, on the immediate technical problems of war-time food production which do not call for further research. The members of the panel are: Prof. F. L. Engledow (cereals and crops), Prof. J. A. Hanley (soils), Prof. H. D. Kay (dairying), Sir John Russell (plant nutrition), Prof. J. A. Scott Watson (general agriculture), Sir George Stapledon (grassland), Dr. T. Wallace (nutrition of horticultural crops), Dr. S. J. Watson (grass and fodder conservation), and Dr. H. E. Woodman (livestock and nutrition). The Secretary of State for Scotland will consult the agricultural colleges and the research institutes in Scotland on any technical questions on which their advice may be desired.

The Spirit of Adventure

There is no greater need in our time than the development of the capacity to weigh evidence and form sound judgments, and, having formed independent judgments, to have the reliance to stand by them. Although the main objects of Surgeon-Commander G. Murray Levick in leading expeditions of school-boys into uninhabited wilds is to widen outlook and to foster the spirit of adventure, one of the chief results must be the encouragement of independence and self-reliance; and no praise can be too high for the enthusiasm and skilled planning which has induced him to shoulder the responsibility of organizing and conducting seven such expeditions for the Public Schools Exploring Society which he founded in 1932. Three of the expeditions have been to Lapland and four to Newfoundland, which affords just those great areas of unmapped and uninhabited country which suit the needs of the young explorers.

SUPPLEMENT

Vol. 144 SATURDAY, SEPTEMBER 30, 1939 No. 3648

SHORT REVIEWS

Agriculture and Horticulture

Seed and Potting Composts

With Special Reference to Soil Sterilization. By W. J. C. Lawrence and J. Newell. Pp. 128. (London: George Allen and Unwin, Ltd., 1939.) 3*s.* 6*d.* net.

THIS lucidly written and well-illustrated book forms a report of the authors' experimental work designed to overcome difficulties experienced in making mixtures or composts of soil, complicated by the necessity of sterilization to prevent fungal diseases. A close scrutiny of the available materials was followed by tests of various methods and apparatus used for soil sterilization, on a larger scale suitable for commercial purposes, and on a smaller scale convenient for amateur gardeners. The more frequent causes of unsatisfactory results are listed in the text, and the methods are critically evaluated.

Two thoroughly tested standard composts are recommended. By the judicious use of powdered chalk and superphosphates, added after sterilization of the loam, satisfactory growth of the seedlings of numerous plants has been obtained in the first compost; in the second compost, used for many pot plants, nitrogen is provided in organic form by horn and hoof grist, but it has been found necessary to supplement this, especially for pot-bound plants, by the addition of nutrients relatively rich in nitrogen in solution. This solution is prepared from a proprietary general fertilizer with the addition of ammonium nitrate or sulphate.

The success of the author's methods at Merton and the growing and widespread adoption of their procedure in the industry form the best notice of their work, which has already enhanced the reputation of the John Innes Horticultural Institution held by practical growers.

The Study of the Soil in the Field

By G. R. Clarke. Second edition. Pp. 192 + 1 plate. (Oxford: Clarendon Press; London: Oxford University Press, 1938.) 6*s.* net.

MANY improvements have been made in the second edition of Mr. Clarke's book. It is unique among English (and most other) books on the soil in treating the subject entirely from the point of view of the student in the field and virtually ignoring the existence of the laboratory chemist and physicist. The true pedologist, says the author, should study the soil as an organism evolving under the influence of its environment, rather than as a subject for very impure chemical experiment.

Mr. Clarke tends to be somewhat dogmatic in his statements, and the inexperienced student will have to exercise care in accepting as facts what are expressions of the author's personal but usually well-founded opinions. Half the book describes the system worked out and used at Oxford for making and recording observations in the field, and the other half various systems of soil surveying and mapping used in different countries. Readers in some of these countries may object that their particular system has not received full justice, but what is lost in justice is gained in the simplicity of description which Mr. Clarke employs.

The book is intended to be carried in the pocket of the field worker, and will form a very valuable addition to his equipment.

Practical Lawn Craft

By R. B. Dawson. (Agricultural and Horticultural Handbooks.) Pp. 300 + 21 plates. (London: Crosby Lockwood and Son, Ltd., 1939.) 15*s.* net.

THE outstanding feature of this invaluable book is the thoroughness with which every detail connected with lawn craft is discussed. The combination of wide practical experience with exhaustive experimental work is evident throughout, and no aspect of the problem is too insignificant to be considered. An important feature is the comparison of the different management necessary for various types of sports grounds and for aerodromes, coupled with diagrams of the lay-out in several cases. The value of the book is much enhanced by the chapter on turf upkeep in other countries, which serves to correlate the various problems and to render the data of more general application. Amateurs and professionals alike owe a debt of gratitude to the author for his masterly presentation of a subject of such general interest.

Anthropology and Archæology

Catalogue of Demotic Papyri in the British Museum
Vol. 1: A Theban Archive of the Reign of Ptolemy I, Soter. By Prof. S. R. K. Glanville. Pp. lii+73+13 plates. (London: British Museum, 1939.) Paper, 33s.; cloth, 35s.

ALTHOUGH the collections of papyri in the British Museum contained demotic papyri so long ago as 1834, very little from them has been published. The catalogue which has been prepared by Prof. S. R. K. Glanville, using the short catalogue of Sir Herbert Thompson as a basis, will be completed in three volumes, of which the first, now issued, consists of a series from a single archive relating to a property at Thebes; the second will cover the literary documents, and the third will contain business and legal documents.

The collection of documents in the first volume dates from the reign of Ptolemy I Soter, with the exception of four receipts for payments, which fall in the reign of Ptolemy II Philadelphus. All are concerned with the history of a small property (or its owners) over a period of twenty-three years, during which time no less than nine persons successively acquired some sort of legal interest in it. What, however, is especially interesting is that the British Museum texts link up directly with other texts in the Rylands Library, in Philadelphia, and elsewhere, which take back the history of the estate for another quarter of a century, making up a record of its vicissitudes and of those of the family connected with it for just under fifty years. This material which, in addition to its reproduction, has been transcribed, translated and edited with a detailed commentary by Prof. Glanville, not only provides much interesting information in regard to neighbourly relations and the construction of dwelling houses in an ancient Egyptian city, but also affords a glimpse of the Egyptian theory of 'ancient lights'.

Racial Proverbs
A Selection of the World's Proverbs arranged Linguistically. By Dr. Selwyn Gurney Champion. Pp. cxxix+767. (London: George Routledge and Sons, Ltd., 1938.) 35s. net.

Proverbes et dictons Syro-Libanais; texte arabe, transcription, traduction, commentaire et index analytique
Par Prof. Michel Feghali. (Université de Paris: Travaux et mémoires de l'Institut d'Ethnologie, Vol. 31.) Pp. xviii+850. (Paris: Institut d'Ethnologie, 1938.) 187.50 francs.

(1) THE collecting of proverbs and gnomic sayings of the various peoples and nations of the world is an entertaining hobby; it is also an important subject of ethnographical research. For those who find it merely an entertainment it may be said that Dr. Champion's collection, to which he has devoted many years, is wider in scope and geographical distribution than any other of the same character; and it is provided with a full apparatus for the convenience of the reader in tracing any particular saying or phrase desired. Brief statements or analyses by different hands deal with the proverbial lore of each country or people; while Dr. R. R. Marett has some remarks to offer on the question of the proverb as an element in cultural studies. It must be said, however, that while some of these introductions are excellent—that on the Arabian proverb is an instance in point—not all are the work of authors of equal skill and authority. Indeed, one writer makes the remarkable admission that until three months previously to the time of writing he was unaware that the people with whom he deals had any proverbs at all!

Nor is the collection of proverbs itself above criticism. For English readers unacquainted with the original language or with the people, a literal translation is of little value unless the English equivalent, if there is one, is added. The least satisfactory section is the Greek, in which quotations from the poets appear as proverbs without remark, and no distinction is made as to whether the source is ancient or modern Greek. Scientifically, it is to be feared, as Dr. Marett seems to hint, this collection of proverbs can have little value. A proverb without commentary to explain its meaning and the conditions of its use cannot afford the assistance it should to an understanding of the mentality of its users, or throw light on their customs and beliefs.

(2) By way of contrast readers may turn to the second volume mentioned above—a detailed and extensive record of proverbs and sayings current in certain parts of Syria, in which are given original text, translation and detailed commentary. The result is a very complete picture, necessarily unsystematic, of the mentality, daily life, social relations and beliefs of the people.

Biology

Sveriges Skogsinsekter
Av Ivar Trägårdh. Pp. xii+509. (Stockholm: Hugo Gebers Förlag, 1939.) 20 kr.

WE welcome the appearance of a second edition of this standard work on Swedish forest insects. Its author, Dr. Ivar Trägårdh has been, for nearly thirty years, a prolific and enthusiastic student and writer on the subject of forest entomology. In this time he has made a name for himself as an authority of high rank. He is a familiar figure at international congresses, and has thus become known personally to many English entomologists.

The first impression upon looking through this volume is the excellence of its letterpress and the wealth of its illustrations (some 570 in number). These latter are nearly all examples of the half-tone process, and the majority are either original or borrowed from various already-published writings by the author. The book is divided into twelve chapters and, as might be expected, the most extensive is devoted to the order Coleoptera, while in the last five chapters the theory and practice of forest entomology are discussed. At the end there are diagnostic keys to the identification of forest pests under each kind of tree, the insects being quoted under their vernacular names. A reliable, practical and scientific book of this kind, in its new edition, will doubtlessly be welcomed in Sweden in view of the great importance of forestry in the national economy. In other European countries a German translation would be an undoubted advantage. Finally, it may be added, almost all the English forest pests will be found to be discussed within its pages.

A Laboratory Introduction to Animal Ecology and Taxonomy

A Laboratory Guide with Keys prepared with Particular Reference to Freshwater and Terrestrial Habitats of the Deciduous Forest Region in North America. By Prof. Orlando Park, Prof. W. C. Allee and Prof. V. E. Shelford. Pp. x+272. (Chicago: University of Chicago Press; London: Cambridge University Press, 1939.) 10s. net.

THIS handbook is written for the naturalist, and is intended for those taking introductory college courses, interested amateurs and high-school students. Its object is to train the student to identify the terrestrial and freshwater animals of the Chicago area, to study their habits, to experiment with them in a simple way, and to find out what is known about them from books. References are given in each section, and there is an extensive bibliography. Problems are set to stimulate further investigation. There are synoptic keys, carried as a rule only to orders, and the student is encouraged to construct his own key by means of an exercise based on ten species of the local snail Polygyra. Pratt's "Manual of Common Invertebrate Animals" and Ward and Whipple's "Fresh Water Biology" are then used for the identification of genera and species. Statistical methods are lightly touched upon and a section on cave animals is included. A glossary of technical terms used in the keys supplements the explanations found in the text. There are seventeen clear line-drawings, mostly by T. J. Daggy. The pages are threaded on ten metal runners which keep the leaves flat when the book is open, but are somewhat awkward to manipulate. The book gives an admirable presentation of the subject.

Flora of Devon

Phanerogams, Vascular Cryptogams, Charophyta. Promoted by the Devonshire Association. Edited by Rev. W. Keble Martin and Gordon T. Fraser, with the assistance of Rev. Thomas Stephenson and Francis M. Day. Pp. xv+787+8 plates. (Arbroath: T. Buncle and Co., Ltd.; London: Wheldon and Wesley, Ltd., 1939.) 25s.

THE editors of this "Flora of Devon" are to be congratulated on the care and attention they have given to this long-awaited volume. Some seven hundred pages of print are devoted to a detailed study of the distribution of the plants found in the county, which for the purposes of this survey has been divided into two vice-counties (following Watson), eight districts and twenty-three sub-districts. Under each species and sub-species is given a list of the places in which it is or has been found and the records of the species in the district. This has entailed a careful study of the specimens in the herbaria in the county, consultation with the systematists who are specialists in the different groups, and an examination of the relevant literature, of which a bibliography is given.

The result is a very complete and careful record of all the data relating to each species and subspecies, which is grouped in accordance with the "London Catalogue of British Plants" (eleventh edition). For the specialist and the systematist the book should be of immense value. Its appeal and scope would, it appears to the reviewer, have been widened had the details given for each plant been somewhat curtailed, thereby allowing of more than forty pages for the introductory portion, which seems to be of more value to the general reader and student. The meteorological, geological and ecological data which are outlined in these first few pages are of great interest and some portions, at least, might have been expanded, to group, for example, the plants under localities, and not, as is found later in the book, the localities under the plants. Out of some eight hundred pages, more than twenty might, with effect, have been devoted to the ecology of the county. J. C.

Experiments in Plant Physiology

A Laboratory Text-Book. By Dr. Walter E. Loomis and Dr. Charles A. Shull. (McGraw-Hill Publications in the Botanical Sciences.) Pp. xiv+213. (London: McGraw-Hill Publishing Co., Ltd., 1939.) 12s.

THIS book consists of the first part of the authors' "Methods in Plant Physiology", which has been revised and rewritten. There are sections on colloids, water-relationships of the plant, photosynthesis, respiration, reserve foodstuffs, water-cultures, growth and tropisms, while a few experiments on growth substances have also been included. While most teaching physiologists, doubtless, will always prefer to devise their own teaching experiments, the present work is remarkably suggestive of fundamental practical work well within the capabilities of most intermediate and general class students. Two pleasing features are the questions added at the end of most of the sections, and the many references to recent literature (nearly all in English) on which the experiments have been based. The consequence should certainly be that the student will be induced to see beyond the actual experiment he has performed, and will try to relate it to the results of modern research.

One would have wished to see more attention being paid to various tests for reserve foodstuffs. A weakness of the book is the failure to include details of practical work on the physiology of the fungi: experiments on the effects of growing moulds on different carbohydrates, or at different temperatures or on media of various dilutions, should form part of any advanced course on practical plant physiology. But apart from this major criticism, it must be said that the authors have produced a very useful book which can confidently be recommended to university and college teachers.

Chemistry

Mellor's Modern Inorganic Chemistry

Revised and Edited by Dr. G. D. Parkes in collaboration with Dr. J. W. Mellor. Pp. xix+915. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1939.) 12*s*. 6*d*.

THIS new edition of Dr. Mellor's well-known book is practically a new work, the arrangement and text having been drastically changed. It is now more systematic and will be found much easier to read by junior students, although some readers who know the original work may regret the omission of the digressions which stamped the book with an original character. The first part now deals with theory, then come seven chapters devoted to hydrogen, oxygen, carbon, nitrogen, sulphur and the halogens, and their principal compounds, and then the remainder of the book discusses the other elements and their compounds in the order of the periodic table. The salts are now described under the metals. Most of the diagrams are new or have been redrawn, and some are not very satisfactory, essential parts being omitted, and in at least one case the diagram does not correspond with the description. In the description of atomic structure, the presence of electrons in the nucleus is postulated in the text.

The new edition of "Mellor" is a straightforward text-book of intermediate and pass standard which will undoubtedly maintain the popularity of the original work. The type is larger and clearer than that of earlier editions.

Casein and its Industrial Applications

By Edwin Sutermeister and Frederick L. Browne. (American Chemical Society Monograph Series, No. 30.) Second edition. Pp. 434. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1939.) 32*s*. 6*d*. net.

THIS book tells all about casein—a material which continues to increase in importance as an industrial raw material: there is much progress to record in the twelve years since the first edition. Casein is used in glues, in paper-making, in paints, in the leather industry, in foods and medicines, etc., and there are chapters under each of these headings packed full of information. The importance of casein as a plastic does not lessen in spite of the many alternative plastic materials. A remarkable coloured plate shows objects fabricated from casein.

The chemistry, manufacture, analysis and storage of casein also receive attention. There is a short note on synthetic textile fibres from casein, which concludes with the forecast that artificial wool fibre will eventually attain the commercial importance of rayon.

There are ten contributing authors, including the two whose names are on the title-page.

A Higher School Certificate Inorganic Chemistry

By Dr. E. J. Holmyard. Pp. xii+529. (London: J. M. Dent and Sons, Ltd., 1939.) 5*s*. 6*d*.

BY allocating space to individual topics roughly in proportion to the frequency with which those topics appear in examination papers, and keeping those sections which deal with stock examination questions within such limits as may enable the candidate to reproduce them or their substance in half an hour, and also by omitting or only briefly recapitulating work up to School Certificate level, the author has been able to present the material for Higher Certificate students in a relatively small compass. Examination questions are not given. The book is divided into two parts, the first containing theory and the second an account of the elements dealt with in the order of the Periodic Table. There is a short section on the electronic theory of valency. The tests for the important metals are given. Preparative details are only briefly stated, but manufacturing processes are described in the important cases in some detail. Dr. Holmyard's book is clearly and attractively written and contains a well planned course of the appropriate standard. A good feature is the presentation of equations for all the important reactions.

The Fundamentals of Chemical Thermodynamics

Part 1: Elementary Theory and Electrochemistry. By Dr. J. A. V. Butler. Third edition. Pp. xv+271. (London: Macmillan and Co., Ltd., 1939.) 7*s*. 6*d*.

THE general plan of the new edition of this book remains the same as that of former editions, but some sections have been revised. These include the chapters on electrochemistry, a simplified treatment of gas reactions, and a short section on semiquinones in the chapter on oxidation-reduction potentials. The book is very clearly written, and provides an excellent introduction to the subject for chemical students.

Engineering

Hydraulics

For Engineers and Engineering Students. By Prof. Frederick Charles Lea. Sixth edition. Pp xii+757. (London: Edward Arnold and Co., 1938.) 21*s*. net.

THE issue of the sixth edition of Prof. Lea's "Hydraulics" is a remarkable event in these days, when the pace at which engineering science develops is such as in a few years to put out of date the great majority of treatises. In the thirty years since it first appeared, the author has kept successive editions well abreast of and in close contact with the most recent developments, and this has no doubt been in large measure due to the active part he himself has taken in scientific investigations and in the work of the professional institutions Therefore, while the great body of unchanging hydraulic principles and their general applications constitute the main structure and usefulness of this volume, we find that, further to the previous additions, there have been included discussions on formulæ arising out of the most recent work on the flow of fluids in pipes and channels and over weirs. The tables and charts based on these should prove very useful when a coefficient has to be chosen for a particular case. Additions have also been made to show new designs of turbines and pumps, and a description of the latest type of electric-hydraulic forging press is another of the added features which maintain the repute of the book as one of the foremost treatises on the subject of hydraulics.

Essentials of Alternating Currents

By Prof. William H. Timbie and Prof. Henry H. Higbie. Second edition. Pp. x+378. (London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc., 1939.) 11*s*. net.

DURING the last ten years there has been a wide expansion in the applications of alternating current power both for domestic use and in industry. The wide use of static condensers for improving the power factor, and the introduction of more efficient rectifying devices, have made a knowledge of the operating principles of these devices essential to the practical electrician, who is keenly alive to keeping abreast of the latest improvements. The second edition has been prepared with this end in view. Many practical men have forgotten much of the mathematics they studied at school, so the authors devote themselves to simplifying the mathematical wording as much as possible and giving graphical methods which, with the help of simple numerical tables, enable them to solve most of the practical problems they come across with the minimum of labour. The chapters on motors, starters and controllers, and on converters and rectifiers will be found useful to many.

Mathematics

A New Geometry for Schools

By Clement V. Durell. Pp. xvi+572+xxii. (London: G. Bell and Sons, Ltd., 1939.) 5*s*. 6*d*.

MR. DURELL'S "Elementary Geometry" appeared fourteen years ago, and the author has now decided to replace it by an entirely new book, recasting his treatment in the light of his own experience, the suggestions sent to him by others, and the recent Second Report of the Mathematical Association on the Teaching of Geometry. He gives a course from the first stage up to the standard of the School Certificate, developing each group of geometrical facts by the following successive stages: examples for oral discussion, numerical examples, formal proofs of theorems, and a carefully graded and classified set of riders.

Computation and Trigonometry

By Harold J. Gay. Pp. vii+143. (New York: The Macmillan Company, 1938.) 10*s*. net.

THE fifteen chapters of this book cover a wide field. The first three are concerned mainly with computation and contain much useful information on arithmetical accuracy, logarithms and the slide rule. Chapters iv–xii deal with plane trigonometry up to the solution of triangles, whilst the remaining three chapters are devoted to the elements of spherical trigonometry with some interesting applications. All the fundamental formulæ are summarized at the end and occupy no less than five pages. Throughout the text, the student is well supplied with exercises, but no answers to these appear to be provided.

In comparison with the course covered the book is somewhat large, but this is due to the fact that bound up with the text is a revised edition, running into over 142 pages, of logarithmic and trigonometric tables, prepared under the editorship of Prof. Hedrick. Most of these tables are given to five places and include compound interest, compound discount, annuity and American Experience Mortality tables.

Some Notes on Least Squares

By Dr. W. Edwards Deming. Pp. iv+181. (Washington, D.C.: Graduate School, Department of Agriculture, 1938.) 1.50 dollars.

THE method of least squares, developed largely by Gauss, and applied widely by astronomers and physicists in the last century, has taken on a new lease of life with its application to statistical problems. Students approaching the method from the statistical point of view are perhaps not as familiar as could be desired with the work of the older writers, and Dr. Deming is to be congratulated on presenting the subject in a way which stresses the continuity of its development. These notes are a mimeographed transcription based on lectures given by Dr. Deming in the Washington School of Agriculture. As the author points out in the preface, they were not assembled with the idea of forming a complete text on the subject, but they do perform a useful function in directing the student who wishes to go into the theory of least squares somewhat closely. Many numerical examples are worked.

Calculus

By Prof. Frederic H. Miller. Pp. xiv+420. (London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc., 1939.) 15*s*. net.

THIS is an account of the differential and integral calculus, with a chapter on infinite series and another chapter on differential equations. It is intended for American students of science or engineering, and also for those interested in mathematics for its own sake. It covers all the usual elements of the subject, going as far as partial differentiation and multiple integrals. There are many geometrical and physical applications, and more than 2,300 examples. The appendixes contain formulæ from other branches of elementary mathematics and useful tables.

Miscellany

A Vicarious Trip to the Barbary Coast

By Mary Berenson. Pp. xii+146+23 plates. (London: Constable and Co., Ltd., 1938.) 7*s*. 6*d*. net.

MRS. BERENSON, owing to ill-health, was unable to accompany her husband on a trip through Italian North Africa to visit the archæological sites and examine the collections of antiquities in the museums. From the detailed descriptions and the accounts of incidents on the journey, which were conveyed to her in letters, and with the aid of guide-books, maps, and authoritative works of reference, she has constructed an account of her "Vicarious Trip" with illustrations. No one, naturally, will go to such a book for original research; but if they wish for a brightly written, informative account of the ground covered, and people encountered, together with a glimpse of what the authorities are doing to explore the archæological sites and preserve the relics of the past in this country, here they will find at least something to satisfy their desire.

Manuel de la conservation et de la restauration des peintures

(Office International des Musées.) Pp. 310. (Paris: Institut Internationale de Coopération Intellectuelle, 1939.) 150 francs.

SOME little time ago, a committee of specialists interested in the conservation and treatment of paintings met in Paris to discuss these activities in detail, and to agree so far as possible upon standard methods of policy and nomenclature. This book is the result of their labours. The separate contributions have been co-ordinated with the view of obtaining constancy of style: this editorial work has been very ably carried out. However, the various sections are by no means equally successful in their subject-matter; for example, the description of methods available in the restorer's studio is admirable, whereas the information relating to radiography and what it can do is extremely sketchy.

So far as the more truly scientific aspects are concerned, the impression is given that the writers sometimes have little personal experience of the processes involved; there is a lack of contact with things as they are in the laboratory.

The bibliography, in spite of an editorial disclaimer, is restricted, and provides a very narrow view of how much has been accomplished in various countries of the world. The volume ends with an excellent glossary (French-English-German-Italian), which curators and others will heartily welcome.

F. I. G. R.

Forty Acres and Steel Mules

By Herman Clarence Nixon. Pp. vii + 98 + 32 plates. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1938.) 2.50 dollars; 11*s*. 6*d*.

THIS very clear and straightforward account of the emergence of the Southern States from plantation slavery and their subsequent submergence under another kind of slavery, in which share croppers and tenants bleed the exhausted soil to pay their feudal dues to absent landlords and small-town traders, illustrates the immense problems of social reconstruction confronting the American cotton belt. The author paints a most depressing picture of the present 'dark age' and does not minimize the difficulties of bringing light into it. He proposes a comprehensive scheme of social, agricultural and industrial readjustment which reads like sound common sense and would have been unnecessary in a world where common sense had prevailed. The book is very graphically illustrated.

An Introduction to Astronomical Navigation

By P. H. Legg. Pp. xiii + 102. (London: Chapman and Hall, Ltd., 1939.) 10*s*. 6*d*. net.

WITH the increase in range and speed of aircraft, the use of astronomical observations to fix the position, independently of observations of ground objects, has become of increasing importance. When flying above continuous cloud or over the ocean, astronomical observations provide the only means of determining the position. In this elementary introduction to astronomical navigation, the means are described by which a position line can be drawn on a map as the result of an observation of altitude of the sun, moon or a star.

The treatment is very detailed and elementary, no previous knowledge of the geometry of the sphere, of the definitions of astronomical quantities or of methods of navigation being assumed. Yet terms such as 'meridional parts' and 'rhumb line' are introduced without explanation. Some familiarity with navigational tables and with the Air Almanac seems to be presupposed. It would have been more in accordance with the scope of the book to assume no such knowledge, to have explained what data are given in the Air Almanac and why the data are given in the form they are, and to have given some description of various tables and other aids to the reduction of the observations.

The dead reckoning position is employed for constructing the position line. The advantage, when using navigation tables, of using an 'assumed position', near to but not necessarily coincident with the dead reckoning position, is not mentioned.

H. S. J.

Philosophy

Medieval Number Symbolism

Its Sources, Meaning and Influence on Thought and Expression. By Prof. Vincent Foster Hopper. Pp. xiii + 241. (New York: Columbia University Press; London: Oxford University Press, 1938.) 15*s*. net.

THE significance of number goes far beyond the pragmatical uses of computation and the abstract necessities of its mathematical treatment. The Pythagorean tradition of linking number with every human interest, which asserted itself in the mystical developments of neo-platonism as well, found a considerable field of application in the religious interests of the Middle Ages. By symbolism, the abstract is brought into the realm of the concrete, where it is immediately recognizable and meaningful. Thus, the abstract beauty and loving-kindness of the Deity were humanly realized in the person of the Virgin, the concept of which was brought ever closer to sense experience through the artistic media of sculpture and painting. The author endeavours, on the basis of the number symbolism of earlier periods which has been studied at length by various experts, to explain the basis, meaning, purpose, extent and use of number symbolism in the Middle Ages; and has chosen the "Divina Commedia" of Dante as a specific example of his interpretation. Prof. Hopper's work, which is more historical and descriptive than philosophical, might have been strengthened by a discussion of the medieval theories about signs and symbols which are expounded by the leading theologians of the period surveyed. As it is, it will serve a useful purpose in enabling one to understand one of the most original aspects of medieval thought. T. G.

The Kantian Philosophy of Space

By Prof. Christopher Browne Garnett, Jr. Pp. xi + 287. (New York: Columbia University Press; London: Oxford University Press, 1939.) 17*s*. 6*d*. net.

THIS is a valuable discussion of the theories of space due to Newton and Leibniz, the development of Kant's views, beginning with his earliest work, and of some modern theories. As against Leibniz, Kant held that space must be in some sense prior to bodies that move, if there are to be universal laws of motion; as against Newton, that empty space, an infinite no-thing, cannot have absolute reality. Modern views tend to be either Leibnizian or Newtonian, or, if the inherent difficulties are realized, Kantian. Kant finally arrived at two inconsistent theories, but between them they seem to exhaust the possibilities.

Essai sur les origines intuitives du positivisme

Par Dr. Pierre Ducassé. (Bibliothèque de philosophie contemporaine.) Pp. x + 272 + 4 plates. (Paris: Félix Alcan, 1939.) 50 francs.

Méthode et intuition chez Auguste Comte

Par Dr. Pierre Ducassé. (Bibliothèque de philosophie contemporaine.) Pp. x + 620. (Paris: Félix Alcan, 1939.) 80 francs.

THESE two books constitute a sympathetic exposition of Auguste Comte's positive philosophy in relation to his life and the development of his thought. Dr. Ducassé is more readable and less dogmatic than Comte himself. His work should do something to revive interest in a thinker once hailed as the founder of a new universal religion and now too much neglected. As the prophet of the application of scientific method to the study of human life and society, if for nothing else, Comte deserves to be studied.

Physics

Angewandte Kristallstrukturlehre

Ein Hilfsbuch zur Bestimmung von Kristallstrukturen. Von Dr. E. Brandenberger. Pp. vii + 208. (Berlin: Gebrüder Borntraeger, 1938.) 12 gold marks.

THIS volume constitutes an excellent work of reference for theoretical studies and computations accompanying crystal analysis. It contains a clear account of structure-topology which is all too rare. For the rest, the discussion follows traditional lines in dealing with the nature of symmetry, translations, point-groups, space-groups, symmetry axes, and the complete formal solution of spatial systems. The numerous figures in the text are clearly drawn, and some of them (so far as the reviewer's experience goes) are original and decidedly revealing. F. I. G. R.

Proceedings of the Sixth Summer Conference on Spectroscopy and its Application

Held at the Massachusetts Institute of Technology, Cambridge, Mass., July 18–20, 1938. Pp. viii + 172. (London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Ltd., 1939.) 15*s*. net.

IN this volume, spectroscopy is little more than a thread binding together investigations on many diverse problems, physical, chemical, biological, etc. There are thirty-one papers more or less unco-ordinated, covering a wide field of subjects. On one hand, there are purely technical discussions dealing with instruments, wave-length standardization, photometric technique, and the properties of photographic emulsions. On the other hand, there are examples of chemical analyses, ranging to the extreme case of the application of the spectroscope to the detection of crime. The analyses described follow either the well-known method of emission-line spectra or the alternative method of absorption spectra, so useful in the case of complex organic compounds, of proved value, for example, in the standardization of vitamin preparations. One of the most interesting of the papers describes an extension of this type of work in the use of absorption spectra for fixing the structure of vitamin B_1. There is also a note on still a third method of chemical analysis, the use of fluorescence spectra, by which, for example, the presence of bacteriological contamination can be detected in a cigarette. On the whole, such biological applications of spectroscopy seem to stand out in interest, in that they point the way to a large field of future research. H. W. B. S.

The Nature of Crystals

By A. G. Ward. (Blackie's Tracts on Recent Physics.) Pp. ix + 114 + 4 plates. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1939.) 3*s*. 6*d*. net.

THIS is a refreshing little book. It is a very good introduction indeed to the new crystallography, but at the same time there is considerably more in it than that. Above all, it is a revolt—and an exceedingly well-planned one—against the excessive professionalism of science with which we seem to be afflicted. Actually, the reader is conducted skilfully through the subjects of formal and chemical crystal structure, and he is asked to delight in knowing the reasons why materials have the properties which in fact they display. Whether, however, the inquirer will leave his easy chair (as the author requests him to do) and "get busy" with a few crystals, test-tubes and dishes is another matter, but he will be the happier—and the wiser—if he can and will.

Some very sound advice is offered for the making of models, and it is clear that these need be neither troublesome to construct nor unduly expensive.

Naturally, these pages will not by themselves produce a crystallographer, while the theorists might almost deny that the contemplation of natural things can give pleasure. Again, it is all rather more difficult. But Mr. Ward—and Prof. Bernal, with his stimulating preface—have produced something at once original and charming. F. I. G. R.

Physics To-day

By John A. Clark, Frederick Russell Gorton and Francis W. Sears. Pp. vi+634+x. (London: Constable and Co., Ltd., 1939.) 8*s.* 6*d.* net.

On account of the differences in the educational systems of the two countries, an American text-book of elementary physics can seldom be used as a text-book in Great Britain. There can be no doubt, however, of the usefulness of the present volume, by three American physicists, to all teachers of elementary physics. The fundamental laws and principles are set out briefly and simply with plenty of illustration. The outstanding feature of the book is the vitality and up-to-dateness of the linking of physical principles with laboratory experiments and with everyday life. With the increasing use of the epidiascope, the book is worth buying for the 750 illustrations alone. They consist of some conventional diagrams to illustrate physical principles together with many diagrams and actual photographs of simple experiments in progress, photographs of practical applications and portraits of all the famous physicists. As a typical example, the subject of levers is illustrated by a photograph of two men using a long pole to raise a car which has sunk up to the axles in mud. The picture is so clear that an estimate can be made of the mechanical advantage. The lever principle in the typewriter and in commercial scales of the newer pattern without springs is the subject of two very clear diagrams amongst a total of fourteen illustrations on levers.

The mixing of philosophy with physics and a loose use of the word 'why' is in striking contrast with the general excellence of the book. The reader is told that "you, like people of all times, want to know the 'why' of things. . . . Physics . . . aims to give you an understanding of both the 'how' and the 'why' of them". Chapter 1 starts with the question: "Is a solid body *really* solid?" However, the mixing of philosophy with physics, like the mixing of theology with ethics, is a matter of taste, and the volume can be very strongly recommended to all teachers of elementary physics in schools and colleges. W. H. G.

Electricity

By Dr. T. F. Wall. (Home University Library of Modern Knowledge, No. 190.) Pp. 256. (London: Thornton Butterworth, Ltd., 1939.) 2*s.* 6*d.* net.

Dr. Wall's interesting survey of the principles and applications of electricity is a valuable addition to the Home University Library of Modern Knowledge. Even the most recent applications are included. In spite of the condensation essential for the treatment of so comprehensive a subject in so small a space, there is no superficiality. The general reader will here find a trustworthy guide to the remarkable penetration of the use of electricity into every sphere of human activity. Food, clothing, housing, hygiene, health, transport and entertainment are all adequately covered. Simple calculations can be made by the aid of the appendix. The volume would also be excellent vacation reading for university students about to study physics in a degree course, or for those specializing in biological subjects, where electrical apparatus is proving increasingly useful. W. H. G.

Psychology

Psychotherapy

By Dr. Paul Schilder. Pp. 344. (London: Kegan Paul and Co., Ltd., 1938.) 15*s.* net.

Dr. Paul Schilder has given us a very good account of his views on psychotherapy. Generally speaking, his views are psychoanalytically determined, although he is by no means an orthodox Freudian according to the purists. At the same time he incorporates just as much of the work of Jung and Adler as he thinks necessary in his psychotherapeutic technique. He dismisses relaxation as scarcely usable in the everyday approach to the patient. We think this is a pity, as this method does play a part in psychotherapy even although it may be largely suggestive in application. We do not agree with the statement that "the hospital situation makes the adaptation too simple for him" when referring to the psychoneurotic.

A Manual of Psychology

By Dr. G. F. Stout. Revised, in collaboration with the author, by C. A. Mace; with an Appendix by Dr. R. H. Thouless. Pp. xix+708. (London: University Tutorial Press, Ltd., 1938.) 12*s.* 6*d.*

To those of us who were brought up on "Stout" it is a great pleasure to see a fifth edition. There is no alteration from the fourth edition except the addition of an appendix on Gestalt by Dr. Thouless and a note giving Prof. Stout's views.

Dr. Thouless gives a very good brief account of *Gestalttheorie*. Prof. Stout accepts Gestalt psychology in general, but is not satisfied with the Gestalt psychology of sense-perception. The Gestalt psychologists seem to deny much importance to past experience in perceptual processes and to neglect the difference between sensation and perception.

Personality in Formation and Action

By Dr. William Healy. (Thomas W. Salmon Memorial Lectures.) Pp. 204. (London: Chapman and Hall, Ltd., 1938.) 8*s.* 6*d.* net.

The Salmon Memorial Lectures for 1937 were delivered by Dr. W. Healy, director of the Judge Baker Guidance Centre in Boston. Personality is defined as "an integrated system of habitual adjustments to the environment, particularly the social environment".

The author gives a very competent account of the development of the personality in childhood, its actions and reactions in adulthood, and the wider implications which are met with in national and international life.

At a meeting early this year of the Royal Society of Arts, Commander Levick gave an account of the 1938 expedition to Newfoundland, and it is clear from his description that the boys enjoyed the experiences and must have gained enormously from them (*J. Roy. Soc. Arts*, 87, 970, Aug. 1939). In recent expeditions a number of boys from secondary schools have been included in the party, and the Astronomer Royal, who was in the chair, pointed out that the public schoolboys and the secondary schoolboys had a great deal to gain from this contact with each other and from collaboration in such an enterprise.

Field Archæology in War Time

ARCHÆOLOGISTS nowadays for the most part, having other preoccupations, have ceased investigations in the field. Nevertheless, experience in the last war showed that military operations may bring to light evidence which, when recorded with such note of the conditions of discovery as circumstances permit, may point the way, as happened in the Macedonian campaign of 1915–18, to further and valuable fields for further research in later days of more assured tranquillity. The valuable collection of prehistoric antiquities at Salonica is not only an enduring monument to the devotion to archæological studies and the *flair* of those archæologists who served in the forces in that theatre of the war, but also, on the cessation of hostilities, it served as the starting-point of a series of investigations in the Macedonian field which have thrown a flood of light on cultural movement in this borderland of prehistoric Greece. Nor should it be allowed to be forgotten that it was directly out of Dr. R. C. Campbell-Thompson's military service in Mesopotamia, which afforded him opportunity for an archæological reconnaissance, that there grew the joint expedition of the British Museum and the University of Pennsylvania to Ur, at first under the direction of the late Dr. H. R. Hall, and later of Sir Leonard Woolley—as a whole, and in its effect on study of the growth of early civilizations, which is still far from being exhausted, one of the most momentous in a long series of discoveries in the history of archæology.

SUCH opportunities in the field overseas are not likely to recur—indeed it is permissible, without risk of misunderstanding, to hope that they will not. But already on the home front a number of finds, recorded in connexion with A.R.P. and other military or defensive activities, bear witness to the vigilance of local archæologists and their solicitude that any evidence of antiquity brought to light shall not escape record. Among the latest finds reported is a discovery at Canterbury (*The Times*, Sept. 25), where in excavating a trench at the Simon Langton schools, on the site of the White, or Austin Friars' former buildings, material of considerable archæological interest has been brought to light. A passage, built of chalk blocks and believed to lead to the Cathedral, is stated to have been found at this point about twenty-five years ago. The site is also known to cover extensive Roman remains; but unfortunately, the need for haste demanded the use of a mechanical excavator and precluded scientific examination of the stratigraphic record. Most of the relics found were of medieval date, and included massive parts of what are believed to be the base of the Friary buildings, a simple medieval copper ring, a sixteenth-century inscribed German jetton, and human bones in no particular order, as well as an undisturbed east-to-west Christian burial. The copper ring was six feet below the surface in an early, probably medieval, cemetery. Of still greater archæological interest was the evidence of a Roman kitchen midden, from which were obtained much broken pottery coated with soot, some fragments of Samian ware, and quantities of burnt wood. These finds were associated with a bed of oyster shells.

Reports of the Australasian Antarctic Expedition

SLOWLY the reports upon the extensive collections made in Antarctic seas by Sir Douglas Mawson's Expedition of 1911–14 are being completed and published (1, part 3 ; 2, part 4 ; 2, part 8. Sydney : Gov. Printer). Among the zoological contributions are Prof. T. Harvey Johnston's "Parasitic Infusoria from Macquarie Island" which include ciliates from a lamellibranch and a suctorian from an Asellid crustacean, both of which appear to be new to science; an account of forty species of Pycnogonida, among which Decolopoda is not represented, by Dr. Isabella Gordon; and a description by Prof. G. E. Nicholls of seven genera and twenty-six species of Gammarid Amphipods new to science, in a collection which includes ninety species representative of sixty genera.

Earthquake near Smyrna

AN earthquake of considerable intensity shook the district around Smyrna on Friday, September 22. In Smyrna itself more than 200 people are reported killed, many more injured and 5,000 are without shelter. In the surrounding district several villages have been almost destroyed. During the remainder of Friday and Saturday, aftershocks have occurred almost continuously, accompanied by underground rumblings. This region of Asia Minor is liable to earthquakes and earth tremors. Smyrna was affected by an earthquake which was destructive also at Aidin and places in the Meander Valley on September 20, 1899, though on that occasion the epicentre was somewhat to the south of the present one, being then near lat. 37·5° N., long. 27·5° E. A destructive earthquake again affected Smyrna on March 31, 1928, the epicentre on that occasion being calculated from the readings of 96 seismograms to have been at lat. 38·5° N., long. 28·0°E., somewhat inland to the east of Smyrna. Further data concerning the present shock will no doubt be somewhat delayed, though it appears to have been sufficiently intense to have affected seismographs throughout the world.

Other Recent Earthquakes

AN earthquake of moderate intensity was recorded at Kew Observatory on September 15. The *P* waves started at 23h. 21m. 42s. G.M.T. on the seismogram and the epicentral distance has been calculated to be provisionally 2,690 km. On September 18 an earthquake was reported as having had its epicentre approximately 50 miles from Vienna. This shock damaged nearly all the buildings in the small village near the epicentre, and two people are reported killed. On September 20 several earth tremors were experienced in Greece. Early in the day severe shocks rocked the town of Patras, and much apprehension was caused, though there appears to have been no resultant damage or loss of life. Shocks were felt also in several parts of the Peloponnesus, including Pyrgos, though here also no damage is reported. Minor tremors are relatively common in Greece, though shocks such as the one of April 22, 1928, which partly destroyed Corinth, are not so frequent. The last severe earthquake in Greece was probably that of July 20, 1938, which did damage at Scala Oropos and adjacent villages.

Protection of Wild Birds

WE understand that the Royal Society for the Protection of Birds has under consideration the drafting of a Bill to amend and consolidate the existing Acts for the protection of wild birds. Such a measure is highly desirable in view of the complexity of the present laws dealing with wild birds. The general lines upon which new legislation should proceed is indicated by certain resolutions drawn up by representatives of the County Councils Association and of municipal corporations, and referred to in the report for 1938 of the Royal Society for the Protection of Birds: (1) that as the complexity of the existing law had led to difficulties in administration, there was, in the opinion of the Conference, a strong case for consolidation and simplification; (2) that protection should be afforded to all wild birds, their nests and eggs, throughout the whole year, with specific exemptions which should be the subject of further discussion; (3) that meantime the Home Office be asked for its views on the matter.

As earlier attempts have shown, it is no easy matter to draft a Bird Protection Bill which is simple, affords all the protection required, and at the same time avoids the danger of opposition from interested persons who may block its passage through Parliament. But with good will and a willingness to compromise on points not vital to the essential interests of wild birds, it should be possible to draft a Bill which would commend itself to reasonable opinion and obtain the assent of Parliament. On the other hand, possible competition between Bills drafted by different bodies, such as for example the Royal Society for the Protection of Birds, the Scottish Society for the Protection of Birds, and perhaps the Home Office, should not be allowed to obscure the need and demand for new and simplified legislation, or, when conditions are more favourable, to delay its speedy passage to the Statute Book.

Value of Fruit Juices

THE possibility of cessation or restriction of supplies of citrus fruits or other fresh fruit juices from abroad makes some recent work carried out at the Long Ashton Research Station, Bristol, of particular value at the present time (Long Ashton, Ann. Rept. 1938). Canned black currant juice would appear to be of special importance. It has a high content of both vitamin C and iron, and has proved extremely useful in cases of ulceration of the stomach and duodenum or hyperacidity. Similarly, apple juice has been successfully used in the treatment of pink disease (erythrocedema). Information obtained from Switzerland and Germany supports the view of the medical significance of fruit juices, claims being made that they are of benefit in other diseases such as diabetes, inflammation of the lungs or kidneys. The writer suggests that closer co-operation with the medical profession in England is desirable, in order that the true facts and significance regarding the use of fruit juices should be discovered and the danger of any false claims be avoided.

Ordnance Survey Plans

IN a paper prepared for the British Association meeting at Dundee, but not delivered, Brigadier A. B. Clough outlined the recommendations of the report of the Committee appointed in May 1935 to consider the revision, scales, styles, etc., of Ordnance Survey maps. The recommendations may be noted even if delay must now ensue in the fulfilment of some. The principal points are these: (1) that no changes be made in the scales of existing maps; (2) that the large-scale maps be rearranged so as to form a single national series instead of thirty-nine separate county series; (3) that the revision of the large-scale plans be a continuous rather than a periodic process; (4) that a new series of maps be introduced on a scale of 1 to 25,000; (5) that a grid be superimposed on all Ordnance maps. Several subsidiary and consequential recommendations follow, namely, that all large-scale plans should be square, that each 1 to 2,500 plan should cover 1 square kilometre of country, and that the metre should be the unit of measurement for the grid. It is also suggested that additional contours should be added to the six-inch map, and that the practice of publishing archæological maps should be continued.

Research in Freshwater Biology

THE seventh annual report for the year ending March 31, 1939, shows that the Freshwater Biological Association of the British Empire is flourishing. The director, Dr. E. B. Worthington, in his review and forecast, states that in last year's report it was forecast that the year now under review would see the launching of new ventures by the Association, building on the foundation laid down during the previous seven years of the Association's history. Of these new developments, three are of primary importance. First, the investigation of the bacteria of fresh water, financed by the Department of Scientific and Industrial Research, has started and the changes in the bacterial flora of Windermere and other waters have now been followed through nearly a whole annual cycle. Secondly, the investigation of coarse fish, financed by the fishery interests themselves, has commenced, and after a preliminary period of exploring possibilities, a sub-station for this special study has been set up in Cambridgeshire. Thirdly, a scheme for close co-operation between Wray Castle and the former Avon Biological Research, situated in the southern chalk stream area, came into effect from April 1, 1939. Under this scheme the Avon Research henceforth becomes a part of the Association as the "University College, Southampton, Branch for Southern Rivers". It will work under the scientific guidance of the Association while retaining its own individuality of control, and the advantage of being still closely associated with the University College. Thus the position of the Association is improved in every way, and, judging from the report on the work done, one may expect much valuable work in the future.

The Warsaw *Akwarium*

The *Akwarium*, a new magazine published for the information of aquarium keepers in Poland, had run only half the course of its first volume when more serious affairs brought it to an end. The last number (6-7) is a well-balanced guide to aquarium interests, dealing with methods of constructing aquaria, circulating and heating the water; with natural aeration by plants and artificial aeration; and with several of the creatures which have become standard inhabitants of the aquarium. Descriptive articles discuss among other things the alligator, some bizarre varieties of gold-fish, and the Egyptian mouthbreeder, *Haplochromis multicolor*, the curious habit of which is to hatch the eggs and protect the young within the cavern of their parent's mouth. We hope that before long the *Akwarium* may resume publication from Warsaw under happier and more settled conditions.

Social Distribution of University Education

In a paper on the social distribution of university education which was given before the Royal Statistical Society on March 21 (*J. Roy. Statist. Soc.*, 102, Part 3), Prof. Major Greenwood discusses the data of whole-time higher education, with particular reference to social class and such foreign experience as is available. Even with a stringent allowance for the difference of mean intellectual levels, it appears that under present conditions a large number of children of ability fit to profit from higher education do not receive it. Prof. Greenwood, however, concludes that the primary importance of university education, so far at least as concerns whole-time university education, is vocational, and as a matter of parental and governmental philosophy this fact is complacently accepted. On this philosophy no large increase of the whole-time university population should be expected. Data, however, about part-time higher education are incomplete, and the matter is of great importance, because increased leisure, which renders higher education possible for numbers greatly exceeding those before, is distributed through life, not concentrated in a few years of complete leisure. In commenting on the paper, Prof. A. M. Carr-Saunders pointed out that the number of those intellectually fit to profit from university education was very much larger than the number required to recruit the professions. He believed it should be the aim of the universities to bring under their care all who could profit fully from university education.

The Lingard Festival

The festival recently held at Stockholm in commemoration of the centenary of the death of Per Henrik Ling, the founder of scientific gymnastics, was attended by nearly eight hundred athletes from thirty-four countries, who took part in the many displays of various methods of training and education for fitness. The general opinion of experts was that the standard of efficiency was remarkably high and proved that the principles on which Ling founded his system still offered a firm basis for popular physical education, though the details had undergone considerable modification in recent years. The British delegates at the Lingard and the subsequent gymnastic congress included Mr. Kenneth Lindsay, Parliamentary Secretary to the Board of Education, Lord Aberdare and Lord Dawson of Penn as representatives of the National Fitness Council of England and Wales, Lord Burghley, president of the Amateur Athletic Association, and others.

A Big Sunspot

For the third time during September, a large naked-eye sunspot group has occurred. The last of these is a giant single spot crossing the disk between September 22 and October 4 with central meridian passage on September 28·0. Near the east limb the spot had an area corrected for foreshortening of more than 1,500 millionths of the sun's visible hemisphere. This spot is the return of an even larger spot (Nature, Sept. 16, p. 508) which crossed the disk between August 26 and September 7.

The Night Sky in October

On October 1 in the latitude of London, night (sunset to sunrise) lasts for 12·3 hours and on October 31 for 14·3 hours; civil twilight (the sun 6° below the horizon) shortens the night by more than one hour. The moon is new on October 12 at 20·5h. and full (the Hunter's Moon) on October 28 at 6·7h. U.T. There is an occultation of the third magnitude star, β Capricorni, on October 20, the disappearance as seen from Greenwich taking place at 17h. 52·0m. at position angle 42° and the reappearance at 19h. 4·7m. at position angle 282°. On October 28 there is a partial eclipse (magnitude 0·992) of the moon that is partly visible from London. The moon enters the earth's umbral shadow at 4h. 54m., reaches mid-eclipse at 6h. 36m. (13 minutes before moonset at London) and leaves the umbral shadow at 8h. 18m. This lunar eclipse is preceded by a total eclipse of the sun on October 12 visible in the Antarctic Ocean south of Australia, the limits of latitude for the central line of totality lying between 60° 0′ and 81° 28′ south. Lunar conjunctions with the planets occur as follows: on October 13 with Mercury; on October 21 with Mars; on October 25 with Jupiter and on October 27 with Saturn. Mars souths at about 19¼h. in mid-October; Jupiter at 22½h., and Saturn at 0¼h. Saturn is in opposition to the sun on October 22 when the planet's distance from the earth is about 772 million miles. Close groupings of Jupiter's four inner satellites can be seen at 22½h. on October 24 and 25; in the 24-hour interval, satellites I, III and IV have swung from west to east of the planet. On October 19–20, Jupiter occults the ninth magnitude star B.D. –1°3. At Greenwich the immersion takes place at 22h. 3m. and the emersion at 0h. 6m. As the motion of Jupiter is retrograde at the time, the immersion takes place at the planet's west limb. The computed times are liable to an error of some minutes owing to the slow motion of the planet. From a radiant in Draco a meteor shower associated with the comet Giacobini-Zinner (1900) may occur between October 8 and 10. The zodiacal light may be observed before dawn in the middle of the month. On moonless nights it is also worth looking for auroras, for the sun is still active and there is a pronounced seasonal peak in the frequency of magnetic storms in October, another peak occurring in March.

Scientific and Technical Institutions

The rooms of the Royal Astronomical Society in Burlington House, London, have been closed until further notice; all communications should be addressed to the Assistant Secretary of the Society at the University Observatory, Oxford.

The offices of the Royal Society of Arts have been removed to Buxted Park, Sussex; correspondence should be addressed to the Secretary of the Society, c/o Basil Ionides, Esq., Buxted Park, Sussex.

The Institution of Mechanical Engineers is carrying on the bulk of its work at The Meadows, Bletchworth, Surrey, but the Institution building in Storey's Gate, London, will remain open for dealing with personal inquiries and for members or others wishing to make use of the library.

The offices of the Iron and Steel Institute at 4 Grosvenor Gardens, London, S.W.1, are remaining open, and the Joint Library and Information Department will be available for consultation by members and the industries. Two volumes of the *Journal* for 1939 are being issued, in September 1939, and January 1940, respectively. The publication of a *Monthly Journal*, the first number of which was to have been issued in January 1940, has been deferred.

The head office of the Institute of Fuel has been removed to 30 Bramham Gardens, London, S.W.5. The ordinary meetings of the Institute are suspended for the time being, but it has been decided to continue publication of the journal. Mr. H. A. Humphrey will deliver the Melchett Lecture, on "The Supply of Explosives during the Last War and the Early History of Billingham", at a luncheon to be held on October 19.

The offices of the Institute of Physics and the *Journal of Scientific Instruments* have been removed to the University of Reading, Berkshire.

The offices of the Institute of Wireless Technology have been transferred to 25 Firs Drive, Palmers Green, London, N.13; for the duration of the war, examinations will be held only once a year.

Announcements

Contrary to what has already been published, the majority of the departments of the Imperial College are remaining at South Kensington; only the Mining Department is going to Camborne and the Metallurgy Department to Swansea. All other departments are preparing to begin normally on October 10, this being possible through the provision of adequate shelters in the basements.

The Royal Botanic Gardens, Kew, are now open every day from 11 a.m. until 4.30 p.m., but should daylight air raids take place, then no doubt the Ministry of Agriculture will close them again. The plant houses are open from 1 p.m. until 4.15 p.m. but the museums will remain closed. Only three of the gates will be open: the Main Gate, Victoria (opposite Kew Gardens Station) and the Lion at Richmond end. Visitors to the Gardens go there at their own risk, as there are no air-raid shelters in the Gardens.

Dr. E. Palmén has been appointed director of the Thalassological Institute, Helsinki.

The University of Toronto has received from the Rockefeller Foundation a gift of 250,000 dollars, a third of which is to be spent on researches on insulin and dementia præcox.

King Gustav of Sweden has devoted the money collected on the occasion of the thirtieth year of his reign, amounting to five million kronen, to the foundation for the study of paralytic diseases, especially poliomyelitis, and to the campaign against tuberculosis.

An honorarium of a thousand dollars to promote research work in ophthalmology is offered through the International Association for the Prevention of Blindness. The subject is simple non-inflammatory glaucoma. Further information may be obtained from the Secretary of the Association, 66 Boulevard Saint-Michel, Paris.

The Fleming Manufacturing Company, Providence, R.I., has constituted a fellowship for the study of the design, construction, and operation of oil filters in the Mellon Institute. Dr. Glenn O. Ebrey, who has been appointed to the incumbency of the fellowship, received his professional education at Illinois College and at the University of Pittsburgh. During 1931–32 he was research chemist with the Sinclair Refining Company, research and development division, East Chicago, Ind. For the past seven years he has been chief chemist of the Pennzoil Company, Oil City, Pa.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 600.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Nature of the Nebular Red-Shift

FROM an investigation (to be published in *Physica*) of the proper vibrations of expanding spherical space, it follows that—in extremely good approximation—light is propagated with respect to co-moving co-ordinates irrespective of the expansion, except that (*a*) the time-rate of events is slowed down and (*b*) all energy portions decrease, both inversely proportional to the radius of curvature.

The slowing down secures the constancy of the velocity of light and entails the nebular red-shift, which from this point of view takes place *during the passage*. The attempt[1] to decide by observation, whether it is actually due to expansion, rests on two important formulæ, which follow from the new view with great ease. Let l be the linear diameter of a nebula *at the moment of emission* and χ its angular distance from the observer (linear distance divided by the circumference of space), then the angle $d\theta$ between two geodesics of space, pointing at the moment of emission from the observer to the ends of the diameter, is from pure geometry:

$$d\theta = \frac{l}{R \sin\chi}, \qquad (1)$$

R being the radius of curvature at the moment of emission. By the theorem quoted above, $d\theta$ is also the observed angular diameter of the nebula (Hubble and Tolman, equation 3).

Again, let the energy emitted by the nebula within an appropriately chosen unit of time be E_s. It will soon assume the shape of a spherical shell of thickness c (say). Let $R_{\text{obs.}}$ be the radius of space, when this shell reaches the observer. Its surface at this moment is, by pure geometry, $4\pi R^2_{\text{obs.}} \sin^2\chi$. By the theorem quoted above, its thickness then is $c\,R_{\text{obs.}}/R$ and its energy is $E_s\,R/R_{\text{obs.}}$. Hence its energy density ρ is

$$\rho = \frac{E_s}{4\pi c R^4_{\text{obs.}}} \cdot \frac{R^2}{\sin^2\chi}. \qquad (2)$$

ρ is a measure of the bolometric luminosity, observed outside the earth's atmosphere (Hubble and Tolman, equation 4).

My purpose in re-stating here these two important formulæ due to Tolman is to make the following remarks. Both l and E_s refer to the moment of emission, which is different for two nebulæ observed simultaneously. Should l and E_s exhibit a general dependence on R, then it would no longer be reasonable to regard them as *constants*, when equations (1) and (2) are combined (as they actually are) with the hypothesis of uniform spatial distribution of the nebulæ. For the latter, if admitted at all, has to apply to nebulæ which are intrinsically similar at the *same* moment of time—not at such moments as depend on the accidental position of our galaxy.

As regards l, the question is, whether we are inclined to assume (*a*) that the distances between the stars within a nebula behave, on the average, like the distances between two points of a rigid body—say, the ends of the Paris metre rod; or (*b*) like the distance between two distant nebulæ. Clearly the case of the stars is intermediate. To regard l as a constant means to decide for the first alternative. The second one would make l/R constant, giving formula (1) the same form as in the case of a non-recessional explanation of the red-shift (see Hubble and Tolman, equation 3′).

As regards E_s, the possible general decline of the nebular candle-powers has already been mentioned by Hubble and Tolman (see their concluding remarks). To the assumption that the same amount of energy is emitted during every second, there is a peculiarly simple alternative, namely, that the amounts of energy, which *have* been emitted during a second, *remain* equal. On account of the decay of travelling energy, this assumption would mean $E_s \sim 1/R$, which reduces equation 2 to the same form as in the case of a non-recessional explanation of the red-shift (see Hubble and Tolman, equation 4′). I do not mean to suggest $E \sim 1/R$ particularly. I mention it in the way of an example.

These remarks detract nothing from the importance of deciding by observation how $d\theta$ and ρ actually behave, if the photographs are interpreted as assuming uniform spatial distribution. I understand that present evidence points to observed luminosities (ρ) decreasing with distance *not even quite as rapidly* as we should expect (with E_s = const.) from the non-recessional explanation. If that is so, I should say they rather support the recessional explanation, in spite of its predicting a still more rapid decrease of the ρ's. The discrepancy, though greater, can here be removed by assuming the E_s's to decrease with time; an assumption which is very plausible in an expanding universe, which, on the whole, cools down; but not at all plausible in a static one.

The Forbidden ${}^3P_0-{}^1D_2$ Line of O III in the Nebular Spectrum of Nova Herculis 1934

ALTHOUGH the two well-known lines of [O III] λ = 5007 A. (${}^3P_2-{}^1D_2$) and λ = 4959 A. (${}^3P_1-{}^1D_2$) are the most prominent features in the spectra of planetary nebulæ and novæ at the nebular stage, the third line of the triplet, corresponding to the ${}^3P_0-{}^1D_2$

transition, for which the calculated wave-length is λ = 4931·8 A., has not been generally observed. Recently, however, Bowen and Wyse[1] attributed to the $^3P_0-{}^1D_2$ transition the faint line which they observed in the spectra of the nebulæ *N.G.C.* 7027 and *N.G.C.* 6572.

In the nebular spectrum of Nova Herculis 1934, we have also observed, in 1935 and 1936, a rather faint but well-defined radiation λ = 4932 A.[2], but could not find to what it could be attributed. Measurements of our fourteen best plates give the wave-length

$$\lambda = 4932 \cdot 2 \pm 0 \cdot 6 \text{ A.},$$

which agrees well with the predicted wave-length for the third [O III] line. This line has been observed neither by Beer nor by Adams and Joy; but in McLaughlin's table[3] concerning the nebular spectrum of Nova Herculis we find a faint radiation λ = 4932·5 without identification.

Though the intensity of the two lines λ = 5007 and λ = 4959 A. has much decreased since 1936, the line λ = 4932 A. is found again in some plates taken at the Observatory of Lyons during the year 1938. It is perhaps not impossible that the $^3P_0-{}^1D_2$ line is now blended with the faint line λ = 4933 A. of *N V* (6*D*−7*F*); but this line was certainly not present at the beginning of the nebular stage. Thus the attribution of the line λ = 4932 A. to the forbidden transition of O III seems to be not doubtful.

We shall naturally expect to find the same line in nebular spectra of other novæ. On August 8 and 13, 1918, Wyse[4] observed a faint unidentified radiation at λ = 4933·3 and λ = 4932·4 A., in the nebular spectrum of Nova Aquilæ 1918.

According to Condon[5], the transition probability for the $^3P_0-{}^1D_2$ transition has theoretically a zero value, but in a recent paper Pasternak[6] gives a small but non-zero value. The transition probabilities calculated by Pasternak are indeed:

$$\begin{array}{ll} ^3P_2-{}^1D_2 & 0 \cdot 016 \text{ sec.}^{-1} \\ ^3P_1-{}^1D_2 & 0 \cdot 0055 \\ ^3P_0-{}^1D_2 & 1 \cdot 3 \times 10^{-4}. \end{array}$$

Roughly speaking, the $^3P_0-{}^1D_2$ transition should be four thousand times less probable than the $^3P_1-{}^1D_2$ transition. It is impossible to say, without any photometric measurements, whether the observed intensity ratio is or is not in agreement with the predicted value. It seems, however, difficult to admit that the observed line λ = 4932 A. is four thousand times less intense than the line λ = 4959 A. The $^3P_2-{}^1D_2$ and $^3P_1-{}^1D_2$ transitions are due to magnetic dipole radiation, and, according to Pasternak, the probability transitions should be accurate in absolute value to within 25 per cent; on the contrary, the $^3P_0-{}^1D_2$ transition is due to electric quadripole radiation and the corresponding probability transition should be good only to within a factor of two.

Influence of Temperature on the Pressure Broadening of Spectral Lines

IN a former note[1] we reported the results of our researches on the influence of temperature on the broadening of the mercury absorption line 2537 A. caused by helium at constant concentration of both gases. No changes of the line width exceeding the limits of experimental errors were observed. Now we have investigated with the same experimental arrangement the broadening of this line caused by admixture of argon. The constant concentration of mercury was about 6 × 10^{14} atoms per c.c. and that of argon 1·4 × 10^{19} atoms per c.c.

Nearly all absorption spectra obtained show a slight increase of the area limited by the line contour, that is, an increase of the width of the broadened line with the temperature. The increase of area due to the temperature change from 420° K. to 1300° K. was found not to exceed 10 per cent (for different plates this effect varies from −2·3 per cent to 10 per cent, the mean value being 3·6 per cent). This experimental increase does not reach the values calculated on the basis of theories of Lorentz[2] (36 per cent) or even of Weisskopf[3] (18 per cent). Also, as is well known[4,5], the asymmetrical intensity distribution within the mercury line 2537 A., broadened by argon, does not agree with the dispersion distribution given by the above-mentioned theories.

We have observed also another temperature effect, namely, the diminution of asymmetry of the line at higher temperature. Although the temperature influence seems really to exist in this case, both these effects are too small for the exact quantitative investigation with our present experimental arrangements.

It should be mentioned that besides the paper of Orthmann (quoted in our first note) whose results agreed with the Lorentz theory, the same problem has been experimentally investigated also by Hull[6]. The temperature effect on the pressure broadening of the potassium resonance line by nitrogen found by the latter amounts to 1630 per cent of that predicted by Lorentz's theory and 2790 per cent of that predicted by the Weisskopf's theory. Thus these results show even more pronounced discrepancy with the collision damping theories than ours, although their deviation is in the opposite direction to that found by us.

Effect of an Excitation Energy on the Specific Heat of Liquid Helium II and its Relation to the Exchange Effect in a Non-Ideal Bose-Einstein Gas

IT has been suggested that, for the explanation of the abnormal properties of liquid helium II, a division of the molecules into molecules 'at rest' and 'moving' ones is an essential feature[1,2,3]. The free path for collision between molecules of different systems should be very large.

London[4] has directed attention to the fact that an ideal Bose-Einstein gas shows a transition point, which lies at 3·15° K. for a gas of a density and a molecular weight of liquid helium. Moreover, below this transition point the gas allows also a division of the molecules in those condensed in the lowest energy state, and others having a kinetic energy.

However, it can scarcely be expected that the velocity distribution of the moving particles in liquid helium can be identified with that of an ideal Bose-Einstein gas, so that it is not surprising that the specific heat of such an ideal gas[4] does not agree with that of liquid helium. The specific heat should increase $T^{3/2}$, whereas experiments show an increase with, at least, T^{6}.[5]

This difficulty can be eliminated by the assumption of an 'excitation-energy', which must be added to a condensed particle before it can participate in the velocity distribution of the moving ones. The specific heat increases then exponentially at low temperatures. In this way a better representation of the anomaly in the specific heat is obtained.

The existence of such an 'excitation-energy' can be explained on similar lines as the disorder energy in Fröhlich's theory of liquid helium[6]. On the other hand, it may also be derived from the gas model, as a consequence of the theory of a non-ideal Bose-Einstein gas below its transition temperature.

Here the excitation energy is due to the effect of exchange, which gives rise to a different interaction when molecules are in the same and when they are in different states. This effect leads to important corrections in the specific heat below the transition temperature, as then many particles will occupy the same, namely, the 'condensed' state.

A more detailed discussion will be published in *Physica*.

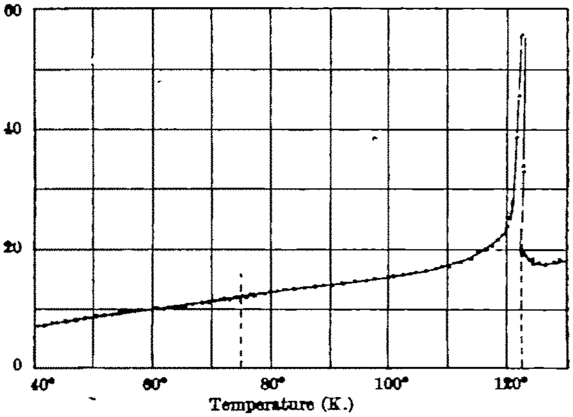
Specific Heat of a Substance showing Spontaneous Electric Polarization

VARIOUS authors[1] have investigated the specific heat of Rochelle salt, the best-known example of substances showing spontaneous electric polarization, but the results obtained so far have been somewhat contradictory. In some of the experiments a small anomaly at the Curie point (the upper limit of the Rochelle electric temperature region) was observed. Very little is, however, known about any thermal effects at the lower limit of the Rochelle-electric region. This temperature has sometimes been called the 'lower Curie point', and it has been suggested[2] that it should be marked by an anomaly in the specific heat.

We have now determined the specific heat of potassium dihydrogen phosphate which shows Rochelle electricity in the temperature region between 75° and 122° K[3]. The result of this investigation is given in the accompanying graph. It is evident from our measurements that there is no trace of any anomaly at the 'lower Curie point'. This means probably that the apparent disappearance of spontaneous electric polarization towards lower temperatures is due to a 'freezing-in' of the dipoles; that is, their inability to orientate themselves below a certain temperature owing to lack of thermal motion in the lattice. It seems, therefore, misleading to describe this temperature as a 'lower Curie point'.



A strong anomaly was observed at the Curie point (122° K.). Owing to the very gradual rise of the specific heat at the onset of this anomaly, an accurate evaluation of its energy content seems difficult. While these experiments were in progress, measurements of the specific heat at the Curie point were reported by Bantle and Scherrer[4] and Stephenson and Hooley[5]. Whereas our values in this temperature region agree well with the results of the latter authors, they differ considerably from those of Bantle and Scherrer. These authors observe the anomaly at 114° K. and give much higher values for the specific heat.

A full report of our experiments will be published elsewhere.

A Particular Mode of Fission of the Uranium Nucleus

As has been reported by one of us[1], uranium fission products can be collected by the recoil method many hours after the end of the irradiation of uranium by slow neutrons. This phenomenon can be explained in the simplest way by the assumption that one or more of the fission products are radioactive gases, of more or less long life and coming somewhere in the middle of the β-transmutation chain. To test this assumption we have performed the following experiments.

About 20 gm. of sodium pyrouranate placed in a glass tube between two cotton-wool plugs was irradiated by slow neutrons from a radio-thorium plus beryllium source equivalent to about 400 millicuries radon plus beryllium during seventeen days. One hour forty minutes after the irradiation had been interrupted, the glass tube with sodium pyrouranate was connected to a water pump and a stream of pure air (radon-free) was passed through it during 50 minutes to remove any radium emanation and the gaseous products of fission, which might have been accumulated in the uranium. Then a glass tube with pure silica-gel cooled to the temperature − 110°C. was placed between the tube with pyrouranate and the water pump and a stream of pure air was passed through the system for four hours. The silica-gel was then treated by hot dilute (1 : 5) hydrochloric acid to which some barium, strontium and lanthanum salts were added. The solution was filtered under suction and a complete chemical separation of lanthanum, barium and strontium was performed. The lanthanum, barium and strontium precipitates were found to be radioactive and showed the following half-life periods : La + K, $T \sim 30$ m., $T \sim 9$h. 30m., and $T \sim 45$h. ; Sr, $T \sim 20$m., $T \sim 7$h. 30m. and one isotope of much longer period ; and Ba, $T \sim 10$h. and $T \sim 50$h.

To find out whether the gaseous radio-elements are in the middle or at the beginning of the transmutation chain, we have separated the fission products of uranium from uranium oxide irradiated for 36 hours by slow neutrons from a cyclotron. The intensity of the neutron beam was equivalent to about 30 curies of radon plus beryllium. We were able to collect, from the walls of the vessel in which that preparation was contained, the products of transformation of the gaseous radio-elements.

These two experiments show definitely that there exist two new fission processes of uranium under bombardment by slow neutrons, with radioactive isotopes of krypton and xenon as intermediary products of the fission, coming in the middle of the transmutation chain[2].

Further experiments will be made in order to estimate the half-life period of these new radioactive isotopes of krypton and xenon and to search for the beginning of these transmutation chains.

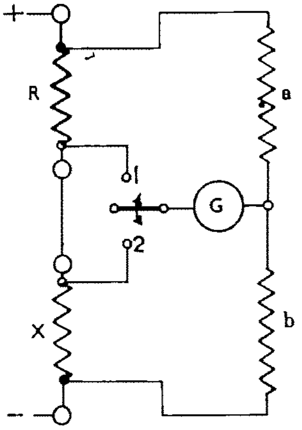
Comparison of Resistances of Four Terminal Resistors

THE only precise method given in the standard text-books for the comparison of the resistances of four terminal resistors is the Kelvin double bridge, and it appears to be the only one used for this purpose. The method described below is at least as precise and should, in my opinion, be as well known.

The circuit is shown in the accompanying figure, in which R and X are the standard and unknown resistances respectively ; a is a fixed resistance, conveniently one of the ratio arms of a standard bridge and b is the variable arm of the bridge.

With the switch on contact 1 a balance is obtained and a second balance with the switch on contact 2. If the values of b for the balances are b and b' respectively and r is the resistance between the inner potential terminals, we may write :



$$R.b = a(X + r) \text{ and } b'(R + r) = X.a.$$

Hence

$$\frac{R}{X} = \frac{a(a + b')}{b'(b + a)}.$$

This method has the following advantages over the double bridge, (1) less apparatus is required, (2) the effective sensitivity of the galvanometer is greater, and (3) no current passes, at balance, through two of the four potential terminals.

Inactivation of Diethylstilbœstrol in the Organism

IN previous reports[1] it has been demonstrated that the sex hormones (œstrone, progesterone) are rapidly rendered inactive in the organism. If a rat is injected with 1,000 I.U. œstrone no more than 1–2 per cent of this substance can be recovered from the organism by organic solvents after a period of forty-eight hours. In contradistinction to this, the hormone esters (œstronebenzoate, œstradiolbenzoate) are very largely recovered. These findings have been corroborated by Laqueur[2], who was able to demonstrate at the same time that the hormone esters remained deposited at the site of injection. They do not undergo slow decomposition in the blood, but are slowly absorbed from the site of injection.

We proceeded to investigate the behaviour of 4 : 4′-dihydroxy α-β-diethylstilbene (diethylstilbœstrol) which was described by Dodds, Golberg, Lawson and Robinson in 1938[3]. The authors, in a most instructive descriptive sketch, demonstrated the resemblance between these œstrogenic substances and œstradiol. Hence we compared the inactivation of stilbœstrol with that of œstradiolbenzoate and some other œstrogens.

Infantile rats were injected with 1,000 I.U. of œstrogenic substance dissolved in 0·1 c.c. of oil. After forty-eight hours the animals were killed and an attempt was made to recover the œstrogenic hormone from the whole body of the animal by my method[1], especially devised for this purpose. The hormone yield is seen in Table 1.

TABLE 1.

Œstrogenic substance	In the body	In the excreta
Œstrone	1–3 per cent	0 per cent
Œstrone benzoate ..	80 " "	Not examined
Œstradiolbenzoate ..	40 " "	1 per cent
Œstrone methyl ether[4]	70 " "	5 " "
Stilbœstrol	25 " "	25 " "

These experiments show that roughly 50 per cent of stilbœstrol can be recovered and that, in this respect, it resembles the hormone esters. It differs from those substances, however, in that half the amount is eliminated in the excreta.

We further investigated the question whether the slow decomposition in the organism is due to storage at the site of injection, or whether the substances are subject to slow decomposition during their circulation in the body. We injected stilbœstrol and other œstrogenic substances (1,000 I.U. in 0·1 c.c. of oil) into the hind-leg of infantile rats, killing the animals after forty-eight hours, and extracted separately the anterior and posterior half (without viscera). The result wás that stilbœstrol was exclusively found in that part which contained the site of injection (Table 2).

TABLE 2.

Œstrogenic substance	Anterior half	Posterior half
Œstradiolbenzoate ..	0	40 per cent
Œstrone methyl ether	0	70 " "
Stilbœstrol	0	25 " "

The experiments lead tothe fo llowing conclusions :

(1) In contrast to œstrone, stilbœstrol is only rendered inactive in the organism to a small extent, resembling, in this respect, the hormone esters.

(2) Similarly to the hormone esters, stilbœstrol remains deposited at the site of injection for a considerable time (depot formation) and from there it is slowly absorbed.

(3) Stilbœstrol is distinguished from the hormone esters by the fact that large amounts are eliminated in the excreta, particularly in the urine.

While after absorption the hormone esters are rapidly rendered inactive in the organism, this is not the case with stilbœstrol. In the excreta large amounts of the active substance are found. The fact that the organism is unable to inactivate considerable amounts of stilbœstrol probably helps to explain its eventual toxic activity (compared with œstrone) particularly if large doses are used.

Estimation and Occurrence of Keto-Acids in Green Plants

ACCORDING to the present conception the keto-acids occupy a central position in the synthesis of amino-acids. Attention has been paid especially to the 'fundamental keto-acids', namely, oxaloacetic acid and keto-glutaric acid, since the amino group of aspartic and glutamic acids formed from them is transferred to other keto acids. In green plants, however, keto-acids other than oxaloacetic acid—the presence of which in the growing legumes has recently been demonstrated in this laboratory[1]—have hitherto not been found, evidently due to the absence of suitable methods.

Lately we have developed the following technique for the determination of keto-acids in plants.

Caustic soda solution and fine quartz sand are added to plant material[1]. The mass is crushed in a mortar and 2-4-dinitrophenylhydrazine solution, strongly acidified with hydrochloric acid, is added to it. The mixture, the pH of which is less than 1, is allowed to stand for one hour at room temperature, whereupon anhydrous sodium sulphate is added until the mass is dry. The mass is extracted with ether in the Soxhlet apparatus. The ether solution, which contains the dinitrophenylhydrazones formed, is shaken with sodium carbonate solution. The solution is then made acid with hydrochloric acid and the hydrazones are again precipitated from it by allowing the solution to stand for three days in the ice-box. The precipitate is separated, dissolved in alcohol and hydrated according to Tafel[2] but at near to 0° C. with sodium amalgam. Amalgam must be added in small quantities to the reaction solution. Thereby the hydrazones are decomposed so that the keto-acids form the corresponding amino-acids as a reduction product. Alcohol is distilled away *in vacuo* and the rest is dissolved in water. The amino-acids formed are determined in the solution. By means of the method in its present form, 80–90 per cent of the keto-acids are found.

In the above manner we have succeeded in finding and determining oxaloacetic acid, keto-glutaric acid and pyruvic acid in growing peas and red clover. For instance, in an experiment with red clover there were found 42 γ keto-glutaric acid, 18 γ oxaloacetic acid and 12 γ pyruvic acid per one gram of fresh material. Investigations are being continued also with non-legumes. The method is applicable also to the determination of keto-acids in animal material and micro-organisms.

A detailed account of the experiments will be given in the *Biochemical Journal*.

Effect of Ethylene on *Mangifera indica*

THE variations in the chemical changes of the respirable substrate accompanying the process of fruit development and ripening of the different varieties of the tropical fruit *Mangifera indica* were investigated with the view of finding out the nature and the response of the substrate to the different methods of storage. Such investigations would provide helpful information for devising methods of storage of this delicate and easily perishable fruit. Accordingly, investigations as to the changes in the respirable substrate under the different conditions of storage were planned and carried out, first at a lower temperature of 8–12° C., secondly in ordinary room conditions of 28–32° C., and thirdly the effect was examined of different concentrations of ethylene gas as a means of artificial ripening.

The presence of ethylene gas is detected in developing *Mangifera indica* by stunted growth of pea seedlings in an atmosphere produced by ripening mangoes. The effect of ethylene on pears by Hansen[1,2], on lemons by Denny[3], on bananas by Wolfe[4], and on tomatoes by Work[5] has been studied; but the chemical changes brought about in the metabolites of the fruit have not yet been clearly understood. Hansen and collaborators have found the effect of ethylene on pears to be more marked at a certain period of the maturity of the fruit and found that the rate of respiration, the rate of starch hydrolysis and the concentration of the total and reducing sugars increased.

In *Mangifera indica* we found that the effect of ethylene is more marked in the pre-climacteric phase of the fruit, and in the post-climacteric phase the effect is not pronounced. This effect is marked by a very rapid increase in the respiration rate, by strong hydrolysis of starch and increase in total and reducing sugars and decrease in titratable acidity and alcohol insoluble residue.

Some of the results showing the amount of respirable substrate obtained at the end of a period of nine days experiment from various samples of different treatments (calculated on the basis of original substrate concentration as 100) are given in the accompanying table:

Substrate	Original substrate concentration	At the end of a period of 9 days			
		Un-treated (control)	Ethylene treated		Cold storage
			0 1%	1 0%	
1. Starch ..	100	36 09	10 49	26·29	56 86
2. Total sugar ..	100	443·90	775·70	612 10	302 80
3. Reducing sugar	100	325 00	491·60	416·60	385·83
4 Titratable acidity (expressed as citric acid)	100	55·60	17·60	17 50	94·06
5. Alcohol insoluble residue ..	100	42 17	27·03	37·84	77 80

In cold storage the trend of chemical changes is in the same direction, but the process is appreciably slowed down. The respiration rate increases markedly in ethylene treated fruit. The vitamin C content decreases as the fruit ripens and it decreases also in storage. The effect of ethylene on vitamin content is not yet clear and work on other tropical fruits is in progress. The effect of ethylene seems therefore to be of a respiratory nature. It initiates a chain of chemical reactions in the available substrate of the fruit, and the effect of ethylene reaction is in turn dependent on the nature of the substrate provided according to the stage of the maturity of the fruit.

Detailed results of these investigations are in course of publication in the *Transactions of the Bose Research Institute*.

Neural Mechanism of Sexual Behaviour in the Female Cat

FEMALE cats in spontaneous or induced œstrus display a characteristic behaviour which may be divided into: (1) courtship activities (playful rolling, rubbing, calling, crouching with pelvis raised, and 'treading'), and (2) the after-reaction (vigorous or frantic rolling, rubbing, squirming, and licking).[1] Bard[1] has shown that extirpation of the neocortex does not change the specific pattern of the sexual response. It was my aim to determine if this peculiar performance of the female cat during 'heat' is conditioned by the activity of an encephalic 'sexual centre' or if some typical components of the complex behaviour could still be elicited from the spinal cord after transection of the brain stem below the medulla.

It is self-evident that, among the reactions mentioned above, only those the accomplishment of which is not dependent on the integrating mechanism of standing and equilibrium are suitable for this kind of experiment. Two reflexes fulfil these conditions: raising of the pelvis, and 'treading'. Treading consists in a rhythmic slow or rapid marching movement of the hind legs with flexion of the thigh and knee and dorsal flexion of the foot, as soldiers mark time. This is obtained by gentle tapping of the perineum. During the course of the investigation another reflex apparently characteristic of 'heat' was observed: when the perineum is tapped on one side the tail is swept towards the other and maintained there until the stimulus ceases, uncovering the whole perineum. This is the natural attitude of the female cat in œstrus when approached by a male. These three reflexes were used as tests for 'heat' in the spinal cats.

The investigation was carried out on thirteen cats, eight of which were normal, in the beginning or towards the middle of their breeding season. Five were ovariectomized during the breeding season and studied towards the end or after the same. In all the spinal cord was transected at the level of the first cervical segment, artificial respiration applied, and the cat kept warm on a heating pad. From three to six hours after the transection, when the spinal shock had subsided, the sexual reflexes were tested on the animal held in crouching position, hindlegs flexed, chest touching the table. Of the eight normal cats, all but one showed a complete positive response to tapping of the perineum. Vaginal smears and the condition of the ovaries indicated œstrus, pro-œstrus or metœstrus. The one negative result was obtained on an old female with anœstrus smear and smooth ovaries. She showed as the only response an elevation of the pelvis. Of the five animals ovariectomized three months previously, three were not injected with œstradiol. Their response was negative as regards treading and tail movements. Two of them showed some raising of the pelvis. When tested before the transection no response whatever could be elicited. The other two ovariectomized animals were injected twice during six days with 1 mgm. œstradiol (Schering Progynon *B* 1939); when they exhibited typical sexual behaviour the transection was made. Reflexes similar to those obtained from the normal cats on heat were obtained from them.

These experiments demonstrate that some components at least of the sexual behaviour are short arc reflexes, comparable to the scratch-reflex, which can be elicited independently of the higher centres, but the occurrence of which depends strictly on hormonal conditions. It seems, therefore, that the existence of a hypothetical 'sexual centre'[1] should be accepted with caution, and then not so much as a pace-maker under the influence of which unspecific activities of the spinal cord are transformed into specific sexual reactions, than as a mechanism co-ordinating certain independent activities pre-existing at different levels of the brain stem. Dempsey and Rioch's[2] failure to obtain sexual reflexes from decerebrate cats may be explained by the extensor rigidity which follows the mesencephalic transection, rhythmic reactions (as treading) and reflex raising of the pelvis requiring for their performance a normal balance of muscle tone.

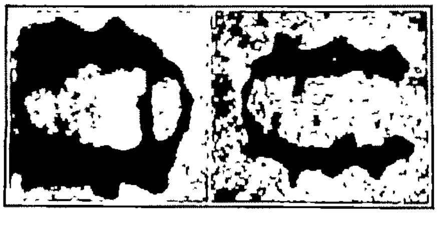
Abnormal Mitosis in Tobacco Plants Forming Hereditary Tumours

Tobacco species hybrids *Nicotiana glauca* ($n = 12$) × *N. Langsdorffii* ($n = 9$), *N. paniculata* ($n = 12$) × *N. Langsdorffii*, *N. suaveolens* ($n = 16$) × *N. Langsdorffii*, etc., formed hereditary tumours[1-4] all over the plants when they were as old as 4–7 months. Each plant of the amphidiploid *N. glauca* × *N. Langsdorffii* (= *N. Vavilovii*; $n = 21$) also formed hereditary tumours at about the same age. In searching for the cause or causes of tumour formation[4-5] I also examined the frequency of the abnormal mitosis in longitudinal sections of root tips of old *N. Vavilovii* plants. I counted normal late anaphases and late anaphases with chromatin bridges and obtained the following figures in studying 752 cells of five different plants which formed hereditary tumours: 21·4, 12·2, 10·7, 8 and 4·2 per cent anaphases with at least one chromatin bridge. 264 anaphases of the maternal plant *N. glauca* and 232 anaphases of the paternal plant *N. Langsdorffii* were also studied. No chromatin bridge was found in these anaphases.



Anaphases with chromatin bridges found in the amphidiploid *N. glauca-Langsdorffii* plants that formed tumours.

Abnormal mitosis, and in particular the formation of chromatin bridges, found in the amphidiploid *N. Vavilovii* does not seem to be due to its polyploid nature, because in studying 72 anaphases of the autotetraploid *N. glauca* no chromatin bridges were found.

The procedure of mitosis in the amphidiploid *N. rustica* ($n = 24$) × *N. glauca* (= *N. rugla*; $n = 36$) was also studied. (This amphidiploid does not form hereditary tumours.) In studying 116 late anaphases of one plant of this amphidiploid I found in four of them chromatin bridges, that is, in 3·4 per cent of the cells. This is a somewhat lower percentage than (though very close to) the smallest one found in the fifth tumour-forming plant; but still high enough when compared with that of the normal species (0 per cent). Tumour-forming plants, however, have on the average a considerably higher percentage of abnormal mitosis. Chromatin bridges represent bicentric chromosomes, resulting, most probably, from exchange of parts between non-homologous chromosomes.

A causal interpretation of tumour formation in the light of these studies can be advanced in the following way. Daughter cells resulting from cells with abnormal mitosis in general and from such with chromatin bridges in particular should have abnormal genetic constitutions. Although such cells may have a lower rate of cell division, their number should be gradually increased, because the process is irreversible, so that the older the plant is the greater percentage of cells with abnormal genetic constitution it should have. When the percentage of the cells with abnormal genetic constitution is considerably increased, determination and differentiation processes become abnormal, so that the plants form tumours (meristematic and parenchymatic tissues) instead of normally differentiated shoots and organs. The formation of abnormal shoots ('bud mutations') in about 12–18 per cent of the plants in some lines of *N. Vavilovii* is also conditioned by abnormal mitosis.

A 'Safe' Fluid for Museum Use

The general practice of using ethyl alcohol as a preservative fluid for museum specimens has several disadvantages. At the present time when we are faced with the possibility of high explosives and incendiary bombs damaging museums, the inflammability of alcohol naturally causes much concern to the staff of such institutions. Ten years ago[1] I directed attention to a preservative fluid, first used by W. Pampel[2], for storing specimens of insects for several years with the tissues soft and in good condition for subsequent dissection. I gave this medium the name of 'Pampel's fluid' and its composition is as follows:

Glacial acetic acid	4 parts
Distilled water	30 parts
Formaldehyde	6 parts
95 per cent alcohol	15 parts

For several years past I have abandoned the use of alcohol for preserving insects and many other arthropods in favour of Pampel's fluid. This fluid is in every way superior to ethyl alcohol, being cheaper, does not need replacement so often and does not cause undue hardening, besides preserving the tissues in a better condition. It is, furthermore, non-inflammable.

I have advocated its use to a number of zoologists and others, and may add that one recent biological expedition preserved almost all its specimens in Pampel's fluid with complete success. It has the drawback that in the case of vertebrates, echinoderms and many of the higher crustaceans, the acetic acid naturally acts upon the calcareous skeleton; but for the vast majority of invertebrate animals this disadvantage does not arise. I recommend that a beginning be made in the use of this fluid with as little delay as possible. Many alcohol-preserved specimens can be transferred into it and it can be adopted for new specimens that it is desired to preserve. It should, at least, be given an adequate trial for a few years.

The Ancestors of the Eutheria

IN a short article on the ancestors of the Eutheria, published in NATURE of September 16, p. 523, Dr. Abbie lays considerable stress on a novel interpretation of the phylogenetic history of the corpus callosum of the brain. Dismissing the generally accepted interpretation, based on the classical studies of the late Sir Grafton Elliot Smith, he states "it has been shown that in reality the corpus callosum has appeared in quite a different manner". For his evidence Dr. Abbie relies on certain topographical observations which he has published in the *Journal of Comparative Neurology* (70, 9; 1939). Whether Dr. Abbie's interpretation is correct or not, it should be pointed out that his evidence appears inconclusive to several other comparative neurologists. Indeed, in a forthcoming paper by Prof. F. Goldby, to be published in the *Journal of Anatomy*, Dr. Abbie's views on the evolution of the corpus callosum are subjected to serious criticism.

Points from Foregoing Letters

E. Schrödinger directs attention to the fact that in an expanding universe (*a*) the diameters of the nebulæ, (*b*) their intrinsic luminosities, may quite reasonably be assumed to depend on the state of expansion. If it is true that their observed luminosities decrease with increasing distance a little too slowly even for the non-recessional explanation of the red-shift, then the recessional one has to be preferred anyhow. For though the discrepancy here becomes greater, a plausible assumption as regards (*b*) will easily remove it.

The forbidden ${}^3P_0 - {}^1D_2$ line of O III, the transition probability of which has a small but non-zero value, has been recently identified in the spectra of two nebulæ. J. Dufay and Miss M. Bloch attribute to this transition the rather faint but well defined radiation $\lambda = 4932 \cdot 2$ A. which they have observed in the nebular spectrum of Nova Herculis.

H. Horodnicзy and A. Jabłoński find that the influence of temperature on the width of the mercury absorption line 2537 A. broadened by argon is smaller than that predicted by the theories of Lorentz and Weisskopf. However, a small temperature effect seems to exist; increase of temperature causes a slight increase of the width and diminution of the asymmetry of the line.

J. and K. Mendelssohn have measured the specific heat of potassium dihydrogen phosphate between 40° and 130° K. No anomaly occurs at the so-called 'lower Curie point', and it is concluded that at this temperature the mobility of the dipoles freezes-in. A strong anomaly occurs at the upper Curie point.

Two sets of experiments on the disintegration of uranium by slow neutrons have been carried out by W. G. Chlopin, M. A. Paswik-Chlopin and N. F. Wolkov. In one set, a uranium salt was exposed to slow neutrons for seventeen days, and the products separated by chemical means; in the other, the exposure was 36 hours and the products of transformation of the gaseous radio-elements were collected from the walls of the reaction vessel. It is claimed that radioactive isotopes of krypton and xenon are formed as intermediate products in the fission of uranium by slow neutrons.

A single bridge method for comparing the resistances of two resistors of low ohmic value is described by A. Glynne. Two balances are effected and the formula for calculating the ratio of the resistances is given.

By experimenting with infantile rats, B. Zondek and F. Sulman have shown that stilbœstrol is only rendered slightly inactive in the organism. Thus it differs from œstrone, but resembles the hormone esters. Also like the latter, stilbœstrol remains at the site of injection for some considerable time and is then slowly absorbed. Unlike hormone esters, stilbœstrol is eliminated in large quantities in the excreta.

A. I. Virtanen, A. A. Arhimo and H. Suomalainen describe a method for determination of keto-acids in plants. The method is based on the formation of 2-4-dinitrophenylhydrazone and its reduction with sodium amalgam in alcohol solution to amino-acids corresponding to the keto-acids. In this way ketoglutaric acid, oxaloacetic acid and pyruvic acid have been determined in plants.

B. K. Kar and H. N. Banerjee have found that the effect of different concentrations of ethylene gas on *Mangifera indica* is more pronounced in the pre-climacteric stage of the developing fruit than in the post-climacteric phase. The effect is seen in the rapid increase of the respiration rate, strong hydrolysis of starch, increased concentration of total and reducing sugars and decrease in titratable acidity and alcohol-insoluble residue. The action of ethylene seems to be of a respiratory nature, and is dependent upon the available substrate, which depends on the stage of the maturity of the fruit.

According to J. P. Maes, sexual behaviour can still be obtained from the spinal cord of female cats in heat when all connexions with encephalic centres have been severed.

RESEARCH ITEMS

Northern Paiute Bands

THE Northern Paiute, once occupying parts of Nevada, Idaho, Oregon and California, belong to the Mono-Paviots dialect of the Plateau Shoshonean language. Although almost everyone writing about these Indians has testified to the existence of bands among them, no one has troubled to ascertain systematically their number, names, or territorial extent. So long ago as 1870, the difficulty of dealing with the Paiutes was recognized by the authorities of the United States as due to the fact that they had no tribal organization, but were divided up into bands of from 50 to 200, each under the nominal leadership of individuals elected by themselves, each band acting independently, although they recognized that they were linguistically and culturally related, and considered themselves as all members of one tribe. The basic unity of the Northern Paiute appears from the fact that they pictured exact boundaries dividing themselves from surrounding tribes, whereas interband divisions were often vague and indefinite. Band territories consisted of a relatively productive area and its environs. In spite of some laxness, the bands had recognized possession of certain tracts, piñon ranges, lakes, streams and hunting grounds. If other Paiutes obtained food there, it was understood that they did so as visitors. Claimed lands seldom overlapped, except where two adjacent bands recognized mutual use of a district. Bands in arid areas travelled more, and spent several months each year as visitors of their friends living in more productive areas. Detailed information concerning each one of the twenty-one bands of the Northern Paiute has been collected in field work and from the literature by Omer C. Stewart (Univ. California: *Anthropological Records*, 2 : 3, 1939) from which has emerged much evidence bearing upon problems of traditional migrations and Paiute affinities.

Protobranchiate Mollusca

THE affinities of the Protobranchiate Mollusca, worked out morphologically by Pelseneer between 1891 and 1911, have now been revised by C. M. Yonge (*Phil. Trans. Roy. Soc.*, B, 230, 79–147; 1939) as the result of a study of living members of the group. Yonge admits three families, the Nuculidæ, Solenomyidæ and Nuculanidæ, the last-named including Thiele's Malletiidæ. In his view "the order Protobranchia established by Pelseneer in 1891 is valid and . . . represents the one unquestionably natural group within the class Lamellibranchia". Yonge studied the mode of life of members of the order at Herdla, Plymouth and Naples, particularly their manner of progression, feeding habits and digestion. The specialization of the foot and its muscles for burrowing into a soft substratum indicates that in this respect they are not primitive, as Pelseneer inferred. The ctenidia are not primarily food collectors and sorters, these functions being undertaken in most by means of a pair of proboscis-like protrusions of the labial palps, which collect organic debris. Typically, the stomach has ciliated sorting and chitinous crushing regions, whence food is passed to the digestive diverticula for intracellular digestion. Yonge asserts that the Protobranchia have been derived from radula-bearing ancestors, but he produces no evidence for this view. The Nuculanidæ differ from the other two families in possessing a *posterior* inhalant current entering through siphons, coupled with a muscular pumping movement of the ctenidia for respiratory purposes. The "Malletiidæ" are Nuculanids which have become modified for life on soft mud in the deep sea. Nuculids are the most primitive Lamellibranchs.

Parasitic Cirripedes of the John Murray Expedition

K. A. Pyefinch has described the Ascothoracica (John Murray Expedition, 1933–34. Scientific Reports, 5, No. 9. British Museum (Natural History); 1939). These parasites have been recorded from a number of hosts, but in this collection they are only in Zoanthids and all belong to the genus Baccalaureus (Broch). Of these, three are new species and one is the *Baccalaureus japonicus* originally described by Broch in 1929. This latter has not previously been recorded from the Indian Ocean. As the author has pointed out previously, the validity of specific distinctions within the genus is a matter of some doubt; since the complete life-history is as yet unknown, what are now regarded as specific differences may merely be due to differences in age of the specimens examined. It is interesting to find that these parasites may themselves harbour parasites. In two cases, once in *B. japonicus* and once in *B. disparcaudatus* from the same station, specimens of a parasitic isopod were found within the cavities of the lateral mantle coils, possibly male and female. A male also occurred attached to the outer surface of the mantle lobes of *B. verrucosus*. These are believed to belong to the family Cryptoniscidæ and are probably a new genus and species, to be described in a later report.

Genetics of the Raspberry

D. LEWIS (*J. Gen.*, 38, 367–379; 1939) describes five new genes in the raspberry. These are *s*, spineless shoots; *b*, shoots without waxy bloom; *x*, red hypocotyl; *g*, pale green leaf; and *d*, sepaloid flowers. The linkage values for genes *T*, *B*, *X* and *G* belonging to one group are *TB* 28·4, *TX* 20·0, *TG* 18·2 and *BX* 36·7. The fact that homozygous hairy plants *HH* are almost completely suppressed suggests that either the constitution *HH* is inviable or that there is a lethal linked to *H*. The occurrence of a large deficiency of recessives in another strain favours the second suggestion. In accordance with Fisher's theory, the only gene (*H*) in the raspberry which is shown to have higher selective value in the heterozygous condition is also the only gene which is polymorphic in the wild.

Triticum sphaerococcum

S. ELLERTON (*J. Gen.*, 38, 307–323; 1939) shows that *Triticum sphaerococcum* differs from *T. vulgare* by one recessive gene *s*. The cytology of the F_1 shows that there is close homology between the chromosomes. The author considers that it is improbable that one recessive mutation should show such diverse and complex effects, and therefore suggests that there is a deletion in *T. sphaerococcum*. The exceptionally high occurrence of speltoid mutants in the F_2 of *T. vulgare* × *T. sphaerococcum* is accounted for by the assumption that the chromosomes which carry the speltoid characters are involved in one of the reciprocal translocations which were observed in the F_1.

Leaf-Spot Disease of Spinach

SPINACH is not subject to many diseases in Great Britain but H. H. Glasscock and W. M. Ware have recorded a leaf-spotting disease caused by the fungus *Heterosporium variabile* (*Gard. Chron.*, August 5). The organism was first described by M. C. Cooke in 1877, from material collected in Welshpool, but it has not appeared again in Great Britain until the present record. Several fungi are, however, mentioned as the cause of leaf-spotting upon spinach in America, and *H. variabile* is among them. The spots are purplish brown, and have conidiophores in the centre portions; they are sufficient in number and extent to cause a serious disease. Cultures have been made of the causal organism, and its characters agree very closely with those of the original description.

A Theory of Mountain-Building

AN important development of the suggestion that convection currents in the earth's substratum may have been responsible for the formation of mountain systems has been made by David Griggs (*Amer. J. Sci.*, Sept. 1939). The theory proposed is synthesized from: (1) the original suggestions of Holmes; (2) the mathematical analyses of Pekeris, Vening Meinesz, and Hales; (3) the author's experiments on solid flow of rocks; (4) thermal experiments and calculations; and (5) a dynamically similar model which demonstrates the action of cyclic convection currents. The structures developed by these currents in the model show striking resemblances to the orogenic structures of the earth. The phases of the convection-current cycle correlate with the three dominant phases of the orogenic cycle: geosynclinal, crustal folding, uplift. The hypothesis is attractive because it seems to satisfy better than any other the three fundamental conditions required of a mountain-building mechanism: (*a*) provision of an adequate compressional force; (*b*) local provision of sufficient contraction for orogenesis; and (*c*) explanation of the intermittent nature of orogenic processes and the threefold character of the mountain-building cycle. In contrast, although thermal contraction may produce sufficient force, it does not seem capable of providing sufficient shortening of the crust to produce the Tertiary mountain systems; moreover, long-distance transmission of compressive stress through the crust to provide localized orogeny is greatly hindered by the viscous drag of the substratum on the over-riding mass. Other forces which have been invoked, such as tidal pull and the *polflucht*, are totally inadequate in magnitude to explain orogenic deformations.

Earthquakes and Crustal Structure near Japan

SEITI YAMAGUTI has recently conducted an investigation (*Bull. Earthq. Res. Inst., Tokyo*, **17**, Pt. 2, 429–442; 1939) to ascertain in which part of the earth's crust near Japan earthquake foci are most frequent. In the neighbourhood of the Japan trench, using the map and bathymetric chart published by the Land Survey Department of the Imperial Japanese Army and the Hydrographic Office of the Imperial Japanese Navy respectively, together with gravity anomalies, the crustal structure was determined and checked by Wadati's seismological results. The thickness of the crust in western Japan appears to be 50 km. and in north-eastern Japan 20 km. The foci of 33 conspicuous earthquakes that occurred in the same Sanriku districts during 1923–38 when the gravity results were being obtained, were as follows: 20 per cent in the subcrustal region just beneath land, 3 per cent in the subcrustal region just beyond the Japan trench and the remainder in the crustal layer or near the boundary of the crustal layer and subcrustal regions on the western side of and about the trench. Near the Inland Sea of Japan, assuming that at a depth of 30 km. isostatic compensation is fulfilled, the configuration of the boundary between the crustal layer and subcrustal region was determined using gravity anomalies. It was then found that 5 out of 7 conspicuous earthquakes between 1923 and 1938 had their foci in the submarine area where isostatic compensation is not fulfilled, and 70 per cent of the 'rather conspicuous' earthquakes, 29 in number, were similarly situated.

Chemistry of the Coloration in Jupiter's Cloud Forms

RUPERT WILDT (*Mon. Not. Roy. Astro. Soc.*, **99**, 8; June, 1939) discusses the action of metallic sodium on both gaseous and condensed ammonia, and suggests this as a possible explanation of the whole range of colours observed on Jupiter. Wildt gives a description of the features of the system sodium-ammonia by the use of the phase diagram taken from a paper by O. Ruff and J. Zedner (*Ber. deutsch. chem. Ges.*, **41**, 1948; 1908) and from the data he draws the tentative conclusion that the coloration of Jupiter's belts may be identified with the brown concentrated solution of sodium formed on the ammonia clouds at temperatures above − 112° C. The absence of conspicuous belts on Saturn is easily understood because this planet has a lower temperature than Jupiter. The hypothesis does not explain the preferentially zonal distribution of the brown shades on Jupiter; specialized assumptions of a meteorological character would be necessary in this case. As the equatorial plane of the planet is in close correspondence with the orbital plane, strong seasonal variations would not exist in the general atmospheric circulation, such as are observed on the earth, and here lies a partial explanation of the distribution of Jupiter's brown shades. A difficulty arises about the small blue areas on the planet because the dilute blue solutions can exist only at temperatures higher than − 78° C., and Jupiter is usually credited with an average surface temperature of only − 140° C. It is supposed that these comparatively rare blue areas are due to the anomalous release of internal energy, a view which receives corroboration from the fact that they appear in nearly all cases during periods of great eruptive activity. A more serious difficulty presents itself when an explanation is sought for the mechanism by which metallic sodium is set free from the sodium compounds that must have been formed during the condensation of Jupiter and are now probably stored in the interior. The author leaves this matter undecided for the present.

TOWN PLANNING AND URBAN CONCENTRATION

THE admirable way in which the evacuation plans have been carried out in the present emergency should not lead us to overlook the importance, when the time comes, for considering the re-planning or further development of our cities on lines designed to minimize such disturbance or upheavals, and the problems which urban concentration presents in civil defence are further reason for attention to this question at the first opportunity. The paper in which Dr. Thomas Adams discussed some economic aspects of urban concentration before Section F (Economics) at the Dundee meeting of the British Association on the very eve of the evacuation could scarcely be surpassed as an analysis of the principles involved.

Dr. Adams pointed out that concentration of industry, economic activities and population in urban centres is essential in order to secure the economic benefits to be derived from scientific progress, and need not militate against social welfare. The advantages of concentration may, however, be impaired by excess or malformation, and in many urban centres such excessive concentration has caused intolerable congestion of traffic, impaired industrial efficiency and overcrowded building development. The most powerful force in causing urban concentration is the existence and potentialities for development of transport facilities, allied with certain favourable qualities in the natural situation, and the planning and control of these facilities are essential to prevent excess.

That New York and London and certain other cities have become too unwieldy to perform their functions efficiently is probably due to their development being artificially promoted, by political agencies and vested interests, beyond that which could occur under the normal play of economic forces. The proper way to eliminate excessive concentration is to promote recentralization on sites with competitive attractions. Even in regard to vulnerability, Dr. Adams does not advocate an excessive attempt to restrict artificially the location and distribution of industry. He argues that if a city, even of the size of London, as a piece of civic machinery, is perfectly designed to perform its functions as an industrial and distribution centre, and if the residue is diffused into compact neighbourhoods and integrated with its industrial areas so as to reduce distances between homes and workplaces, the true solution is to construct adequate defences or even to face evacuation in war time at any cost.

Dr. Adams argues that the steady flow and free movement of street traffic are essential for economic efficiency, and urban areas should be planned or replanned to provide the space required. Further, if the main transport facilities are properly planned and controlled, artificial restriction of the location and distribution of industry should scarcely be required, and provision of ample space for locomotion purposes should simultaneously meet essential requirements of air space and recreation. Economic solutions of these problems largely resolve themselves into questions of transport and land prices. The reduction of costs of transport involves the elimination of unnecessary travel, and the reduction of land prices the elimination of values based on improper or unhealthy uses of land.

The need for scientific investigation of the excess concentration as a first step for a national effort towards its control was stressed by Dr. Adams. Other research is needed to ascertain the best methods of reducing 'friction of space' between producers and consumers of goods and services, and between places of residence and places of work and recreation. Town planning should be based more on the data of the economist and less on the consideration of sentimental values.

Among the major defects in urban growth, Dr. Adams directed attention to the obstruction of the movement of street traffic and the absence of space for standing traffic, as well as to the overcrowding of facilities for passenger traffic and the resultant destruction of nervous energy. He also stressed the overcrowding of population on the land, thus preventing the inhabitants from securing adequate light, air and recreation, and the absence of room for the expansion of industrial plants, markets, etc. Such evils cannot be remedied effectively by the negative process of planning control. Dr. Adams suggested that the ratio of open space in a town for traffic, recreation and space about buildings should not be less than sixty per cent.

CONFERENCE OF LEATHER CHEMISTS

DESPITE the uncertain conditions which prevailed, the Biennial Conference of Leather Trades' Chemists was held in London during August 28–30. The Conference was preceded by a reception of members of the International Society of Leather Trades' Chemists and numerous foreign guests at the May Fair Hotel, London, on Sunday, August 27, when they were received by the president of the British Section, Mr. R. Faraday Innes.

At the opening meeting, the first Procter Memorial Lecture was delivered by Dr. W. T. Astbury, the title being "The Molecular Structure of Fibres of the Collagen Group". The presidential address given by Mr. W. R. Atkin was on the subject of "The Procter Wilson Theory of Protein Swelling in the Light of Modern Ideas of Protein Structure". Prof. P. Chambard of Lyon was elected president of the Society for 1940–41.

During the meeting, it was announced that the Fraser Muir Moffat Medal of the Foundation of Tanners' Research Laboratory of America had been awarded to Dr. Dorothy Jordan Lloyd for her outstanding work in the field of tanning chemistry, and particularly her recent book on "The Chemistry of the Proteins". Among other papers read during the meeting were, "A New Expression for the Buffering Capacity of Solutions" by Dr. V. Kubelka (Brno), "Fatty Spue in Semi-Chrome Leather" by R. Faraday Innes (London), "Studies in Currying" by M. P. Balfe (London), "Precipitation of Natural Tannins with Calcium Hydroxide" by Vl. Němec (Brno), Conductimetric Analysis of Vegetable Tanned Leathers" by S. G. Shuttleworth (South Africa), "Formaldehyde Tannage in Relation to the Constitution of Collagen" by F. O'Flaherty (U.S.A.), "The Chemistry of Formaldehyde Tanning" by Miss W. B. Pleass and Miss J. H. Boews (London), "Reaction between Casein and Formaldehyde" by C. Robinson (London), "A Machine for Measuring the Resistance of Leather to Abrasion" by F. E. Humphreys (London), "Shoe Troubles and Leather Faults" by H. Bradley.

Before the conclusion of the Conference, the following films were shown: "The Inside Story of Lubrication", "Wattle Bark and Extract Manufacture" and "Preparation of Cod Liver Oil".

PROGRESS OF ILLUMINATION

DR. H. W. MELVILLE prepared an evening lecture for the Dundee meeting of the British Association, under the title "New Lamps for Old"

The natural illuminant, the sun, is considered first. We may regard the sun as a 'black body' with a surface temperature of about 6000° C. Being a black body, it emits light of all wave-lengths, but the wave-lengths in which we are particularly interested lie in the visible region from about 4000 A. to 7500 A., for it so happens that evolutionary processes have developed a human optical system which is most sensitive to such a band of wave-lengths.

When we measure the energy emitted by the sun within a small band of wave-lengths, for example, 10 A., and plot the energy as a function of the wave-length of this band of radiation, we obtain a curve with a pronounced maximum at about 5500 A., in the green. Again, the human eye is most sensitive in the region where the sun emits this maximum. Besides radiation in the visible region, there is also radiation at longer wave-lengths in the infra-red and at shorter wave-lengths in the ultra-violet. These radiations cannot be perceived by the human eye, but they can be detected by various physical methods.

It would seem, then, that the production of artificial illumination exactly similar to that of the sun is a simple matter. All we need do is to heat something black to a temperature of 6000° C. But the difficulty is that we cannot devise a means of heating a substance to this temperature, as all known materials either melt or volatilize so quickly that the conditions cannot be realized. Our problem, therefore, is to devise some subterfuge which will get over the difficulty without having to resort to the drastic method of getting radiation similar to that obtained from the sun. As a matter of interest, there is a possibility of doing better than the sun does. So far as illumination is concerned, the infra-red and ultra-violet radiation is wasted. If the energy of these rays could be converted into visible radiation, the efficiency of our source would be appreciably increased.

The goal to be obtained in the search for the ideal source of light is one in which all the energy supplied to the lamp, in whatever form, is wholly converted into visible radiation, with precisely the same intensity and wave-length distribution as that given by the sun. Dr. Melville gives an account of the progress that has been made towards this goal and how far we have still to go.

More than four thousand years ago, it was observed that certain vegetable and perhaps mineral oils, on undergoing combustion, emit visible radiation. Then by using a lamp into which a wick dipped, the burning was easily controlled at the top of the wick. Here then is the first principle of the subject—the conversion of oil into vapour and the subsequent combustion of the vapour. The next development was gas lighting. This phase occurred when it was found that oil could easily be converted into gas, and later when coal was found to undergo a similar reaction.

By allowing a substance to undergo combustion, a sufficiently high temperature is generated to produce visible radiation. If, therefore, we are going to increase the efficiency of our source of light, we must find out what produces the light. An experiment answers this question. The flame of a mixture of hydrogen and carbon monoxide emits only a small amount of radiation in the blue. When the gas is diverted through a bottle containing finely divided carbon, the flame becomes luminous and on close examination the incandescent particles of carbon can be seen describing vortices in the flame itself. The luminosity of the usual gas flame is thus due to carbon. The origin of the carbon in the gas flame is the decomposition of the volatile hydrocarbons present in the coal gas.

The temperature of even finely divided carbon in such a flame is only 1100° C., and therefore its colour does not approach that of the sun. Bunsen improved this by mixing the gas with air and by increasing its pressure. When mantles made of thorium and cerium are used, the light is the brightest. The curves obtained by the so-called Welsbach mixture show that the temperature attained is the highest. The light obtained from an ordinary gas mantle has a distinctly greenish tinge. This proves that it is no longer similar to a black body at the same temperature.

Besides the luminescence emitted by hot interacting gases, there are a number of solid and liquid reactions in chemistry which are accompanied by luminescence at ordinary temperatures. The luminescence of a firefly is a familiar example, but the precise nature of the reaction is not known. Unfortunately, one firefly gives only 1/1600 candle power, mostly in the green and red. For lighting a lecture room of reasonable size, about a million fireflies would be required.

Finally, the electrical methods of producing radiations are considered. The first attempts were made by heating refractory materials by passing an electric current through them. The electric arc between carbon electrodes was one of the first satisfactory sources. Since the temperature of the carbon may reach 5000° C., the light is very similar in quality to that of the sun. But the efficiency is not high and the operation is too complicated for most purposes. The carbon filament incandescent lamp was a poor substitute, as in a high vacuum carbon volatilizes rather easily, with the result that the temperature is only about 1800° C. The tungsten filament was a great improvement, the working temperature of the filament rising to 2400° C. We can in this case use an inert gas like argon or nitrogen, thus making a lamp twice as efficient as the carbon filament lamp. A further improvement can be introduced by coiling the filament on itself.

A still more efficient lamp can be made by introducing a new method, namely, the phenomena accompanying electric discharge in rarefied gases. If a discharge tube be evacuated, it needs a very high potential difference applied across its terminals to produce a flash. By reducing the pressure to about 1/1000 of an atmosphere a much smaller voltage suffices to produce a steady discharge which fills the tube with light. A variety of colours can be obtained by using various gases instead of air. By constructing the interior of the lamp of fused silica and fixing a suitable conducting cathode, the pressure may be increased up to 100 atmospheres with a corresponding increase in luminous output.

The latest type of discharge lamp uses low-pressure discharge, in which the intensity of the ultra-violet radiation is a maximum, and a fluorescent substance which emits visible light under the action of ultraviolet light is put inside the tube. A series of such lamps can be devised with colours which when suitably blended give white light. To obtain white light from a single lamp, a mixture of powders is fused on to the inside of the discharge tube. The new discharge lamps have brought us very close to the perfectly efficient source.

SCIENCE AND THE COMMUNITY

A PUBLIC lecture "Science and the Community" given by Prof. Alex Findlay on September 12, 1938, at the invitation of the Council of the University of Otago, Dunedin, has been published by the New Zealand Council for Educational Research ("Studies in Education", No. 4. London: Oxford University Press). Referring to the achievements of applied science in ministering to the health and material comfort of the people and to industrial efficiency and development, Prof. Findlay points out that science is knowledge and that knowledge can be gained only by persistent inquiry or research, and he urges the importance for the welfare of the country that not merely a few but all the people should become research-minded and recognize with conviction that research is the best insurance of the future. Welcoming the greater attention being paid to the human factor in industry and to the consequences of the impact of science on our social organization, he considers that in proclaiming the great achievements of science we should beware of losing sight of the idealism of science. For the community as a whole, it is not the acquisition of a knowledge of scientific facts that is of chief importance but the inculcation of the spirit of science.

The first great aim of science is the seeking out of truth, and scientific truth is one of the great human values essential for a complete life. Science is, however, not merely an amassing of facts; its spirit is also to be found in the great hypotheses and theories of science, and the cultivation of the spirit of science makes an æsthetic as well as an intellectual appeal, strengthening and perfecting the fulfilment of that other essential factor in a complete human nature, the desire for beauty. Cultivation of the spirit of science is also necessary for the body politic. To cure or ameliorate the evils which flow from the weaknesses to which all democratic government is subject, we must work for a greater knowledge and honesty of purpose, a higher cultural level in the community.

Urging that science is an important factor in the moral and social development of the people, Prof. Findlay stresses the importance of ensuring that the minds of all university students should be opened to scientific truth as revealed in the physical and biological sciences and to recognize the importance of method and facts as well as ideas. For this he does not consider that laboratory work is essential. As regards the place of men of science in the State and in the general life of the community, he suggests that our present dangers are due to neglect of the ethical rather than of the scientific values. While he would not support any plea for a special place for the man of science as such in the councils of government, he urges the duty of men of science to cultivate a rich humanity and to educate their minds to take a wide view and form a balanced judgment, to enable them to take a much fuller share in the common duties of citizenship, placing more unreservedly at the disposal of their fellow citizens that contribution of special knowledge and outlook which their training and studies enable them to make. By cultivating the human values not only of science but also of art and religion, and building into their personalities the qualities of truth, beauty and goodness, scientific men can do much to form a more enlightened public opinion and help in the solution of the educational, social, economic and other problems which face the community. They should strive not merely to bring about a planned order of society with a purely materialistic outlook, but also an order in which individual human nature can find its full expression through the cultivation of truth, beauty and goodness.

UNIVERSITY EVENTS

St. Andrews.—In view of the cancellation, owing to national emergency, of the graduation ceremonial appointed to be held by the University of St. Andrews on the occasion of the visit to Dundee of the British Association, the Senatus Academicus have conferred the honorary degree of LL.D. *in absentia* on the following, who were to be recipients of the degree upon that occasion: Prof. F. T. Brooks, Dr. C. G. Darwin, Sir Albert Seward, Prof. R. V. Southwell, Lord Stamp, Sir Aurel Stein.

Dr. Cyril Dodd, of Durham, has been appointed to the lectureship in natural philosophy in the United College, St. Andrews, which fell vacant on the appointment of Dr. F. L. Arnot to a post in Australia.

SCIENCE NEWS A CENTURY AGO

Travels of Schomburgk and Gould

IN its column of "Weekly Gossip" the *Athenæum* of October 5, 1839, referred to the naturalists Robert Schomburgk and John Gould.

Of the former the journal said: "We have also the pleasure to announce the arrival in London, after an absence of twelve years from Europe, of Mr. Robert Schomburgk, who, during the last four years has been engaged exploring in the colony of British Guiana under the auspices of the Geographical Society, in the course of which time he has twice ascended the Essequibo, and explored that river to its sources, about 40 miles north of the equator; he has also examined the Berbice and Coventyn rivers. . . . During his last journey, on which he was absent about two years in the interior, the traveller crossed the frontier to Fort San Joaquim in the Brazils, and ascended the Caruman mountains; thence returning to Pirára, he journeyed in a north-west direction to Roraima, a remarkable flat-topped sandstone mountain, rising 7,000 feet above the sea; and by a westerly course to Esmeralda, on the Orinoco, thereby connecting his labours with those of Baron Humboldt in the year 1800, and materially changing the position of the sources of that river as laid down in all our maps. Thence descending by the natural canal of the Cassiquiare to San Carlos, he embarked on the Rio Negro and followed its downward course as far as Moura, from which place he ascended the Rio Branco to San Joaquim thus completing a circle of upwards of 2,000 miles, a great part of which was through a country hitherto almost unknown. . . ."

Mr. (afterwards Sir) Robert Hermann Schomburgk was of German birth, being born in Prussia, June 5, 1804. After his explorations in the West Indies and British Guiana, he was appointed Government Commissioner for surveying and making the boundaries of British Guiana establishing the 'Schomburgk line'. Afterwards he was British Consul at San Domingo and at Bangkok. He died at Schöneberg, near Berlin, on March 11, 1865.

Of the naturalist John Gould the *Athenæum* said: "Mr. Gould, another of our enterprising naturalists, gone on a scientific pilgrimage to the very antipodes, and whose proceedings and success we have from time to time been enabled to announce to our readers, has, according to accounts just received, left Van Diemens Land for Southern Australia. He had already collected about 800 specimens of birds, 70 of quadrupeds (several of which are new), more than 100 specimens preserved whole in spirits for dissection, and the nests and eggs of above 70 species of birds, together with skeletons of all the principal forms".

Born at Lyme Regis on September 14, 1804, Gould as a boy lived with his uncle at the royal gardens at Windsor. In 1827 he became taxidermist to the Zoological Society and during the years 1831–37 published works on the birds of the Himalayas and of Europe, the drawings for which were made by his wife, who in 1838 accompanied her husband to Australia, where she died. Gould returned to England in 1840 and afterwards published "The Birds of Australia", "The Mammals of Australia", "A Handbook of Birds of Australia" and "The Birds of Great Britain". He was elected F.R.S. in 1843 and died in London on February 3, 1881.

SEEKING AND SECURING THE PEACE

THE fundamental war aims of France and Great Britain have been stated clearly by the Prime Minister as being "to redeem Europe from the perpetual and constantly recurring fear of German aggression, and to enable the people of Europe to preserve their independence and their liberties". Mr. Chamberlain's clear-cut phrasing expresses without ambiguity the spirit of determination with which the peoples of France and Great Britain have entered on the task which lies before them. It reflects with crystal clearness their resolve to restore to Europe conditions in which all its nations, without discrimination, may live side by side in the firm assurance that each will be free to develop to the full and at will in accordance with its traditions and culture under a settled order, of which the sanctity is recognized and respected as inviolable equally by all.

For the man of science and the student of the modes of development of human societies throughout the ages, this resolve of the people and their leaders is pregnant with hope for the future. In its grasp of realities it argues an appreciation of the rights and dignity of the individual, as well as of the integrity of national units, which while observing every consideration for the expression of that individuality, will not hesitate to demand that in its exercise each will contribute its appropriate share to the common stock—a contribution which will not only recognize the rights of other communities, but will also co-operate to relieve their necessities. For we may rest assured from our experience of the last war that, at the close of hostilities, innumerable social and economic problems will arise to demand with insistence the co-operation of each and everyone for their s
tion, under penalty for failure of the coll

civilization. It is not in this war that there lurks the supreme danger for mankind—no war undertaken in the spirit of a crusade can fail to ennoble, though the individual perish—but in the peace which will follow. The elimination of an aggressor will not solve automatically the difficulties which in recent years have troubled the world and left it at odds with itself. The ending of this striving for dominance will do no more than prepare the way to the search for a remedy for these difficulties. It will make possible co-operative study in the light of an objective and scientifically detached view of the facts and the circumstances from which they have arisen.

In this way alone, and only in such conditions in international relations as it is our aim to establish, will it be possible to exercise a scientific control of future social and economic development, instead of the erratic play of economic forces damned by ill-judged and ill-conceived measures to bolster up a false and misguided conception of national prosperity, or even of national security. Though projected to stem the breakdown of the economic system, many such measures have only accentuated its weaknesses by wrecking the system of exchange and hampering distribution, so that valuable products of soil a
have been destroyed as a glut, and whol
tions have been on the verge of starv
the earth brought forth in plenty.
ment of the *United States*, the ri
in the world in gold, the conventi
exchange which it co
of d

a hundredfold, and probably with many more, which will still await solution 'after the war'.

Those of us who are old enough to remember clearly the outbreak of the two major wars in which the British people have been engaged in the present century—the Boer War and the War of 1914–18—will contrast, not without some amazement, the difference in the expression of popular feeling with which we have entered upon this war—a difference far more impressive in its undemonstrative exhibition of a complete unity of direction in purpose than the ebullient enthusiasm of the cheering crowds of the early August of 1914. Nor has there been any attempt to revive such an outbreak of popular feeling through the incitement of a vague and general statement of aims, an ideal for which we are to fight. We are not even assured, as politicians assured us in 1914, that this is "a war to end war". If we are the poorer in slogans, we are the more direct in purpose.

Yet, as the correspondence now appearing in the daily Press can show, there are those who hold that this direction of purpose might gain in strength and intensity if our ultimate aims were clearly defined. Mr. H. G. Wells, for example, in his letter in *The Times* of September 26, while arguing that "more and more of us are beginning to realize that there can be no more peace or safety on earth without a profound reconstruction of the methods of human living", goes on to assume that the Western world is quite inevitably marching towards a world collectivism. He suggests that we should make a genuine attempt to realize "that phase of world-wide plenty and safety" through a federation of mankind by free and unfettered discussion, simple and sincere, of the various means for the attainment of that end.

In Mr. Wells's view, the failure of the League of Nations to become such a federation of mankind as he envisages, was due to the fact that it
"too conservative of existing things, half-
diplomatic". *Is* not the truth exactly
Its most effective work has been in
esearch, the discussion of scientific,
nomic problems, and the application
to practical problems—witness the
rug traffic in some of
up-

affecting literature, art and science, had for long been the order of the day. The League extended the scope of this co-operation, regularized and systematized it, and provided the machinery and organization for its more effective operation. Here it functioned with a most gratifying and surprising success. On the other hand, it was where it was most novel in its methods that it failed. For in a world of unharmonized peoples, many of whom were passing, or had passed recently, through a reconstruction on the principle of national or racial self-determination, it asked in some measure for an abrogation of a sovereignty either lately won or saved from destruction at enormous cost.

While the student of the forms of civilized society may see that the process of growth in the formation of human communities has been one of constant reintegration in larger and larger social unities—from family or kin to tribe, from tribe to people, from people to nation, and from nation to empire—it may well be that, in the long run, the logical goal of this ordered evolutionary process is the largest integration of all, the federation of mankind. But the time for this is not yet. Not merely is too large a proportion of the world's populations still in a state of retarded development—the populations of India and China alone, of whom a preponderating number is an impoverished peasantry, account for between a third and a half of the world's numbers—but the idea of nationality is too deep-seated as an emotional spring of action to be eliminated by the logical completeness of a theory. Though the excessive and frequently pernicious growth of nationalist sentiment in recent years has proved a setback to social and economic development, nevertheless a strong national tradition may be made a great asset to advancement, as the history of the world has shown.

In the discussion of problems of world-wide import—and all problems of a serious character nowadays tend to be world-wide in their application—in this discussion then, which is inevitable, racial and national traditions and cultures will each contribute a different point of view and a different outlook, whereby discussion will be the more capable of producing ultimate harmony, rather than any attempt to form an organization in which that tradition is likely to suffer a sense of frustration all too soon. For whatever may be the form or the machinery, be it league or federa-
n, through which the peoples of the world will
co-operation which is inevitable unless

the order of civilization is to crumble away, it is not discussion of general principles or machinery, in other words of the form of government and the means to secure it, which will save mankind from disaster, but the scientific study on a co-operative basis of the concrete problems which are vital to the well-being and the very existence of the unit from which the social aggregation is built up, whatever its form—the individual man, woman and child.

THE NATIONAL REGISTER

A NATIONAL REGISTER is, in essence, a continuous census. It is best regarded as a means of obtaining and recording that accurate knowledge of its human resources which the advance of science has made necessary to a civilized community. For more than a century past a periodic census has given us a record, at approximately ten-year intervals, of the numbers and distribution of the population in Great Britain, together with varying amounts of information about its composition as to sex, age, occupations, and so on. These records have become fuller during that time; and there has been pressure to make them also more frequent. A quinquennial census has been authorized, though not carried out. Now, under the stress of war, we have begun the transition from a periodic to a continuous record. Of course, it is not possible to publish continuously; but it should be possible to issue quarterly returns, akin to those now submitted by the registrars-general in respect to births, deaths, and marriages.

The information collected for this first edition of a British National Register is similar to, though less extensive than, that for recent censuses. It is limited to the name, sex, age, condition as to marriage, and occupation of every individual, with an additional column for members of the defence services. The plans for it were made during peace but are being carried out in a country at war, which is probably the reason for the extreme reduction of the form to be filled in by each householder. The most striking omissions are the absence of questions as to nationality, birthplace, workplace, or usual residence for those away from home. The first of these may perhaps be adequately replaced by the register of aliens kept by the police; the others are less urgent at present. But all these, and more, will be needed for a permanent national register.

The new feature which distinguishes this registration from all previous censuses is the provision for keeping it up to date. This takes the form of a legal obligation placed on all persons to notify every change of residence to the National Registration Officer of the district into which they move. Soon this must be extended to notification of all changes that affect the Register, and are not otherwise recorded, such as a change of occupation. The records of all these changes will make it possible to obtain information of increase or decrease of population in every local government district at frequent intervals. Everyone concerned with the administration of local government, or of education, has often felt the need for such information, which will now become available in respect of all the people. It has hitherto been available only in respect of certain groups, such as those on the live registers of the employment exchanges. It is urgently needed by all authorities responsible for public health. For all such services, and for local transport and retail distribution, a National Register will make possible greater efficiency, providing that it is well maintained.

The last full census was taken in 1931. It is, therefore, out of date for many purposes. The need for a prompt stocktaking of all our manpower is now urgent; and the experience of the War of 1914–18 shows that some such register can be invaluable in respect to both military and industrial organization for war and to the maintenance of the national life. By its regimentation and conscription of men and women, the German Reich has already got some corresponding record of its human resources. Not enough is known here about the system used to allow useful comparisons with this British register.

It is unfortunate that the Register was not compiled months ago, before the outbreak of war made the task at once more urgent and more difficult. The evacuation of children and women from large towns, and the parallel removal of many other people will make the early months of the war a time of special difficulty in keeping in touch with the abnormal number of changes of residence. On the other hand, the fact that the Register is to form the basis for the lists of those entitled to food ration cards provides a strong incentive to prompt notification. Even so, the organization for the maintenance of the Register will be very severely tested in the next few months.

This registration is accompanied by the introduction of the personal identity card, which has long been a familiar thing in many European countries, where its value has been well proved. Like the Register, this first identity card is extremely simplified: in fact it is scarcely more than a reference to the register by name and number. But both should become permanent features of our national life; and both will inevitably become more comprehensive. The value of the card is obvious. In normal times, cases of difficulty in the identification of persons suffering from loss of memory, or victims of street accidents, are sufficiently frequent to stress the need for such a document. Only the law-breaker has a real, if not a socially valid, reason for objecting to it. It is interesting to note that it does not bear the name of the country, thus following the tradition of British postage stamps.

The National Register and the identity card are essential to the scientific organization of a civilized community, and should have been introduced years ago. The State which does not know its human resources accurately cannot organize them well; nor can it measure with sufficient accuracy its liabilities to its dependent members and its children. The rapidly increasing complexity of modern life, and the resultant increase in the number, the importance, and the intricacy of the functions of government, national and local, and of other social organizations, make it more and more necessary that their working shall be based on a full and accurate knowledge of our human resources and liabilities. For defence against external enemies, against disease, and against internal disorder, for the supply of satisfactory nutrition to all the population, in fact for all the many needs of social life for which we, as social beings, are dependent on the society of which we are units; it is necessary to have such knowledge as a national register can best provide. Each one of us is, willy-nilly, in some degree his brother's keeper and is affected by that brother's well-being or misfortune, and for the fulfilment of the social duties implied in this relation we need this knowledge.

Of course this does not mean that the mere existence of a national register, however complete and well kept it may be, will ensure social efficiency. Nor can it determine any policy. It may be a basis for the development and application of policies of very different types and aims. It is only a tool, a very valuable tool, for the organization of life in a civilized country. How, and for what purposes, such a tool may or will be used is a matter of national policy that will be determined in the same way as other such policies are decided in Great Britain.

As an example of the matters on which precise information can be obtained from the Register as it is now, we may note the composition of the population, nationally and locally, by age and sex groups. It will be possible to know promptly if, and how far, internal movements such as the so-called 'drift to the south' have left some areas with an unduly low proportion of adolescents and young adults, and a correspondingly high proportion of either or both children and old people, and given to the areas of immigration a badly balanced population of reverse type. Many other examples of such possibilities could be given; but this one is enough to emphasize the value of the Register in enabling us to have accurate information of such social facts in place of uncertain estimates, which have hitherto been checked only by the periodic census.

This is the first attempt at compiling a national register in Great Britain; and, although it has been carefully planned, it is experimental. There can be no doubt that experience of its working will give rise to many suggestions for improvements and extensions intended to make it more useful. After the war, at least one census will be needed as a check on its accuracy, and to strengthen the continuity of our national records by an overlap between the periodic censuses and the continuous register. There will also be changes in the identity card and the record on it. Some day the official mind may grasp the fact that it would be a convenience to the public if such things as this card, driving licences, bank notes, postage stamp books, and other articles to be carried in a man's pocket or a lady's handbag, were made of standard uniform sizes.

The most valuable of all our national resources is the human material. The National Register can help to provide a more scientific basis for attempts to improve its quality, by nutrition and training, to control its numbers, and to make better use of it in the development of the good life for all members of our society.

THE MARIHUANA PROBLEM

Marihuana, America's New Drug Problem
A Sociologic Question with its Basic Explanation dependent on Biologic and Medical Principles. By Prof. Robert P. Walton. Pp. ix+223+12 plates. (Philadelphia and London: J. B. Lippincott Co., 1938.) 12*s.* 6*d.* net.

THE hop plant (*Humulus lupulus*) and hemp (*Cannabis sativa*) are close botanical relatives and each secretes a physiologically active resin. The hop resin is, of course, important in Europe in the manufacture of beer, but hemp resin has found little application, the plant being normally grown only for fibre production. A different state of affairs exists in Africa, the Near East and India, where the resinous exudate of the hemp plant has been widely used (or abused) from remote times for its narcotic properties, under a variety of names according to mode of preparation, the best known of which is perhaps hashish. The virtual absence of hashish addiction in Europe can scarcely be attributed to difficulty of access, since hemp is readily cultivated, particularly in the Mediterranean area, and it has been frequently assumed that temperamental differences between Europeans and Orientals make the euphoric action of hashish less attractive to the former. A similar explanation has been advanced to explain the preference of the Chinese for the languorous dreams of opium rather than the wild ecstasy of hashish.

Viewed in this light, the establishment of the hashish habit in Central America, where hemp, under the name of marihuana, is smoked usually in the form of cigarettes, is perhaps not surprising, nor is the fact that marihuana smoking penetrated to some extent from Mexico into the extreme south of the United States. Astonishing, however, is the enormous increase in the vice which has taken place throughout the United States during the last ten years. There it has assumed almost epidemic proportions and has become a national problem. A particularly dangerous feature of the American situation to-day is the spread of the habit among school children and adolescents, and it is this feature which has made marihuana a subject of moment not only to the Bureau of Narcotics but also to every class of social worker. The increasing attention given to this problem has, of course, stimulated the interest of medical and scientific investigators, since it is clear that a thorough knowledge of the drug in all its aspects is of primary importance in combating the menace of its use.

The literature on the subject of hashish is vast and so heterogeneous in character that it is no simple matter to obtain from it a clear picture of any feature of the subject. Medical and scientific workers will therefore welcome this admirable monograph by Prof. Walton, which provides a survey of our present knowledge of hashish. The lay reader will doubtless find much of interest and value in the chapters dealing with the history and distribution of the vice and its present status in America. As this section, however, comprises but 39 pages of reading matter out of a total of 195, it does not, in the reviewer's opinion, justify the advertising matter on the dust cover of the volume; this at first sight suggests a popular treatment of the marihuana habit rather than a monograph dealing with hemp drugs from a scientific point of view. The section of the book dealing with descriptions of the hashish experience is fairly extensive, but while it is true that the layman might be interested in at least the more colourful literary descriptions of Ludlow and Gautier, it is difficult to see how he would benefit in any way from them.

Of particular value to the professional reader are the chapters devoted to acute and chronic effects of hashish, in which the author has analysed the recorded descriptions of its effect and has carefully classified them; his findings should remove many common misconceptions. Save in extreme cases, deprivation of the drug appears to cause no serious physical symptoms in marihuana addicts, and the tendency to chronic addiction is much less than that observed with the so-called 'white' drugs (cocaine, etc.). These facts, together with the relatively low degree of physical deterioration associated with the use of hemp drugs have, of course, been known for a considerable time, and the Indian Hemp Drug Commission reported that the hemp drugs were considered by many in India to be less harmful than alcohol. Prof. Walton, however, rightly stresses that the most serious aspect of the problem in America is the extent to which the vice promotes juvenile delinquency, serves as an introduction to more dangerous drugs, and increases the use of extreme violence by criminals.

The two chapters dealing with the pharmacology and chemistry of hashish cover practically all the published work on the subject, and there are many references to the original literature. The bibliography is good and the appendix on the nomenclature of the various hemp preparations used throughout the world is most valuable. One feels with the author that although therapeutic applications of Cannabis are at present negligible, the drug is well worth further consideration, since its extraordinary physiological action suggests that a marked increase in therapeutic use may follow the isolation and identification of the active principles.

A. R. Todd.

METALS AND THEIR ALLOYS

Metals and Their Alloys
By Sir Harold Carpenter and Dr. J. M. Robertson. Vol. 1. Pp. xxii + 824. Vol. 2. Pp. xii + 825–1486. (London, New York and Toronto: Oxford University Press, 1939.) 105*s*. net.

THE publication of the present work in two volumes by Sir Harold Carpenter and Dr. J. M. Robertson is an event which merits not only especial mention but also especial consideration. For, as a result of the actual development of our knowledge, works of this kind, if not exceptional or unique, are becoming increasingly rare.

The wide range of subjects under consideration in this work—which is concerned with metals and their alloys, with their constitution, their structure, their treatment from both the thermal and mechanical aspects, and with their properties and uses—together with the monumental qualities of the book, which contains 1,472 pages and the spirit, both theoretical and practical, in which it is conceived, might tempt one to regard it as a treatise. But in actual fact it is no treatise, neither in conception, inspiration, execution or purpose.

A treatise proper may be defined as an exposition, as complete as possible, of the sum total of knowledge and experience concerning the subject under consideration—in this case, the science of metals and their alloys together with practical applications. Such a work is designed to include within its scope every publication on the subject, regardless of relative value; and to present them all as being on the same level. But although the number of publications mentioned in the present work is very large (more than six hundred) the authors have made their selection; for, as Sir Harold Carpenter says in his preface, if the development of present ideas and theories were to be traced and all opinions and criticisms represented, this number would have to be doubled. Thus it is the personal opinion of the authors which is expounded in these two volumes rather than the sum total of published opinion.

In the same way, a critical selection of published works which the authors consider to be the most useful for the purpose in view, has been included.

Furthermore, in view of the accelerated pace of research and the consequent mass of published work, the material labour involved in the publication of a treatise proper would involve the collaboration of a large number of different authors who would divide among themselves the labour of analysis and exposition of the published material. In this way, a treatise proper loses in unity of thought and conception what it gains in the extent and quantity of accumulated documentary material. A treatise is intended to be included in a reference library; but not to be read and meditated over as a whole. It is a tool or instrument, rather than a work of instruction; and seldom possesses either educational or critical value.

On the other hand, the work under review, which has been completed in its entirety by two authors in close collaboration, manages to preserve a remarkable unity of thought and opinion. To me it appears as an achievement of unique educational value, whether to a student in the completion of his studies, to an engineer desiring to keep in touch with the latest advances in metallurgical science, or to a specialist anxious to compare and debate his opinions with those of a master of the subject.

This book might well be included in an academic course; and, as a matter of actual fact, one of the authors, Sir Harold Carpenter himself, occupies the principal chair in metallurgy in England, apart from which he has presided over and directed the investigations of three great technical institutions concerned with metals; namely, the Iron and Steel Institute, the Institute of Metals and the Institution of Mining and Metallurgy. All this is a proof of his exceptional authority and is also largely responsible for the perfection of this book as a whole and for the admirable sequence and co-ordination of the material contained in it. Actually, at the present time, the structure of metals considered from every aspect constitutes the essential foundations of our knowledge when it is combined, on one hand with the chemical composition of the product furnished by the metallurgist and, on the other, with the mechanical and heat treatment effected by the transformer; and finally, with those properties which constitute the very basis of practical usage and application.

At the same time, the work—very justifiably—includes in the preliminary chapters a thorough and careful study of the constitution of metals and their alloys, together with their relations to deformations. This is followed by an examination of properties and treatments. These comprehensive chapters concerned with instruction in general metallography constitute the first volume of the work (Chapters i to x)—a volume which thus expresses its individuality and unity.

Incidentally, the remarkable order in the arrangement of the book as a whole is equally carried out in the detailed presentation of the various chapters; and particularly in those dealing with the deformation of metals, which show clearly, on one hand, the interdependence of the three variables—time, temperature and deformation—and, on the other, the triple aspect of the mechanical problem which they condition: namely, a deformation which is very limited in practice, an important deformation without rupture in cases of mechanical transformation, and a deformation forced to the point of rupture in mechanical experiment.

The principles enunciated in the first volume find their application in the second, which is concerned with those metals and alloys, both ferrous and non-ferrous, which are of the greatest importance to industry. These chapters also are very well balanced.

From the point of view of the instructive value of the work, it is perhaps a pity that the authors found it necessary, in order not to be involved in a long chain of developments, to suppress the historical section dealing with the laborious acquisition of our knowledge of metals and their alloys. An exposition of the kind has a distinct educative value inasmuch as it helps the student and others to realize that this knowledge is not the product of to-day, but has been slowly and painfully amassed over a long period of time. Furthermore, it helps to show him that many of the most modern ideas on the subject were divined or predicted by men of exceptional perspicacity and foresight—men such as Sorby, Tschernoff and Osmond, whose names should live for ever in the minds of successive generations of metallurgists. It is for this reason that the present authors, in their just appreciation and recognition of all those who have in any way contributed to the building of this scientific edifice, have dedicated their book to them.

In the planning and development of the various chapters of the book the pedagogic qualities of the authors have been fully demonstrated. But they appear also in another capacity, as experimenters who have themselves made contributions of the first importance to the subject. Neither the compilers of treatises nor those who devote themselves to the task of imparting knowledge are necessarily at the same time research workers or experimenters. Indeed, the combination is a very rare one. For the builder and architect can quite well work with materials furnished and delivered by others. But Sir Harold Carpenter and Dr. Robertson are both world-famous for their work on metals, and this fact lends an especial interest to the chapters of the book in which they record the development of their own experimental work.

To give one example only. In Chapter xi, where the transformation of the iron-carbon alloys is described, the account is based, for the most part, on three papers of fundamental importance, by Sir Harold Carpenter and Dr. Robertson, which were read at the Iron and Steel Institute between 1931 and 1933 (The Formation of Pearlite from Austenite; The Austenite - Pearlite Inversion; Structural Changes in Hypo-eutectoid Steel on Heating). These papers had been preceded in 1931 by a work of Dr. Robertson's on "The Effect of the Rate of Cooling on the Structure and Constitution of Steel" published by the Mines Department (Publication No. 59 of the Safety in Mines Research Board). For this reason, unfortunately, the work is relatively little known, especially to French readers; and this is all the more regrettable in view of the fact that the work of the French school is both emphasized and appreciated in the paper. It is thus very welcome to find in one of these chapters a description of the whole of the original work done by the authors themselves, illustrated by their exceedingly remarkable photomicrographs.

Thus, two characteristic aspects of the authors' activities—instruction and scientific research—are combined harmoniously to lend a particularly individual quality to this work, namely, the quality of a didactical exposition of the whole of our metallographical knowledge as conceived by them as a result of their own researches and of the study of other published investigations.

The work as a whole constitutes a most valuable synthesis to which, in this branch of science, it would be difficult to find a parallel. A work such as the present one represents an expenditure of effort undertaken in a spirit of enthusiasm. It is a task accomplished as a result of years spent in the calm of scientific meditation and reflection. All this confers upon it an individual and lasting value; and the appearance of the two volumes, the illustrations, etc, are excellent and worthy of the contents.

This is not a book to be relegated to library shelves, but should have its place on the desk or work-table. It is not a mere distributor of information, but a source of creative ideas and researches and therefore rich in consequences.

Albert M. Portevin.

INTRODUCTORY FORESTRY

(1) An Introduction to American Forestry

By Prof. Shirley Walter Allen. (American Forestry Series.) Pp. viii + 402. (New York and London: McGraw-Hill Book Co., Inc., 1938.) 21*s*.

(2) The Nation's Forests

By William Atherton Du Puy. Pp. ix + 264. (New York: The Macmillan Company, 1938.) 13*s*. net.

(3) An Outline of Forestry

By Thomas Thomson and M. R. K. Jerram. Pp. viii + 208. (London: Thomas Murby and Co., 1938.) 7*s*. 6*d*. net.

(1) THIS is the first volume of an "American Forestry Series" which will include other volumes on "The Theory and Practice of Silviculture", "Forest Pathology", "Identification of the Timbers of the United States", "Forest Mensuration", "Forest Insects", "Textbook of Dendrology and Management of American Forests".

The present volume by Shirley Walter Allen, professor of forestry, University of Michigan, expresses its object in the words in the preface, "Forestry is in need of a wider circle of acquaintances". Since there has been a Forest Service in the United States of America for several decades, this displays the difficulties of implanting in the public, as we know in Great Britain, a knowledge and sound appreciation of the value of forests to a country. The author has accordingly aimed, not so much at the instruction of forestry students who intend taking up forestry as their professional work (though as an introduction it serves that purpose) but rather at instructing a reading public.

It may be admitted that Prof. Allen's aim is admirably fulfilled, if we omit the factor of its length. For example, since the "Series" is to include volumes on protection, the sixty-five pages devoted to the subject might have been curtailed.

The plan of the book is indicated by the chapters, as follows: man and the forest, building the country with forests, where our forests are and what they produce, what a forest is, forestry that starts with a forest (a chapter which may well be commended to those responsible for the great existing forest capital in the Colonies under British administration), forestry that starts with bare ground, defending the forests from (1) fire, (2) insects, etc., (3) fungus, pests and the elements, measuring and harvesting, and finally, several chapters on forest policy generally. An appendix is devoted to general statistics.

(2) An even more popularly written book than Allen's "Introduction" is Mr. W. A. Du Puy's "The Nation's Forests", which has an introduction by that eminent forester, F. A. Silcox, chief of the United States Forest Service.

In the introduction, Mr. Silcox writes: "For the most part, those of us who handle forest problems are technical men. We are very close to our tasks. It seems difficult for us to tell, simply but graphically, about the vast public properties entrusted to our care; about what those properties are, how they are used, how—directly and indirectly—they affect the average citizen; how they make more jobs; how they add to the security and stability of families and communities, and increase the permanent wealth of a nation". To some extent Mr. Silcox is correct in his complaint that the forest officer is curiously pen-tied when he wishes to transmit his thoughts on his work and on Nature as he sees it to the public; and commonly the layman does not possess sufficient technical knowledge to paint a correct picture. In the book in question, written for America and Americans, Mr. Du Puy shows that he possesses both knowledge and facility to translate forestry problems into easy, even fascinating, language based on personal investigations.

The author commences by pointing out that each American citizen possesses an 'estate' of one and a third acres—his share of the national forests—and this is supported by the striking photograph of a forest fire, facing p. 124. The photographs form an educative feature of the book. This latter is divided into fourteen chapters, entitled: everyman's forest, when the lumberman came, Nature heals her wounds, which trees to cut, planting forests and sustained yield, erosion control, fire protection and recreation, wild animals, range management and wilderness areas, of which all are well written. Finally, the author deals with products of wood, and State and private forestry.

(3) This text-book is written by two members of the staff of the Bangor Forestry School at the

University College of North Wales—Messrs. T. Thomson and M. R. K. Jerram. The aims of the book are not so clear cut as those of the two American books already discussed. The authors suffer from having attempted too much. They state that their "main object is to provide for students on their initial approach to the subject an explanatory outline of the kind of knowledge they will have to acquire; it is hoped that it may prove useful to others who are interested in the subject". If we consider Chapter iii, on the practice of sylviculture, which forms one fourth of the book, the material dealt with is far beyond the ordinary reader and comes under the definition 'technical'.

In two hundred pages the authors have attempted in reality to cover the whole subject of forestry, as shown by their own table on p. 6, which exhibits their four main divisions: forest policy; forest bionomics, subdivided into the foundations of sylviculture, the practice of sylviculture, and forest protection; forest economics, subdivided into forest valuation and finance, and forest utilization; forest management, subdivided into general considerations, the regulation of the yield and the preparation of a forest working plan.

It is somewhat difficult to say to whom the book will appeal. Most trained foresters nowadays hold the opinion that the above branches of forestry require to be kept apart and considered separately in text-books to be used by the student training for the forestry profession—as in fact is shown in "American Forestry Series" alluded to above. For example, Chapter x is entitled "The Preparation of a Forest Working Plan". This important subject is discussed in some three and a half pages. For the ordinary reader possessing some knowledge of forestry, the book may be commended, as it contains much useful material.

SOME EARLY GANOID FISHES

The Triassic Fishes of Besano, Lombardy

By James Brough. Pp. ix+117+7 plates. (London: British Museum (Natural History), 1939). 20s.

During the Triassic period the ganoid fishes with a gristly skeleton, belonging to the same grade as the existing sturgeons, were gradually replaced by ganoid fishes with a bony skeleton like the surviving Amia and Lepidosteus of North American fresh waters. Links between the two grades have already been recognized among Triassic fishes, and there can be no doubt that the one evolved from the other. The transition, however, evidently took place in the sea, and it has hitherto been studied chiefly when it was beginning (as in the Lower Trias of Spitsbergen, East Greenland, and Madagascar) and when it was almost completed (as in the Upper Trias and Rhætic of Italy and Austria). The ganoids of the Middle Trias—those of the critical period—are still well known only by freshwater forms from Australia and South Africa; and it must be noted that from early geological times onwards fresh waters have always been retreats for life which is no longer in the forefront of progress.

A large collection of marine fishes from the Middle Trias of Besano, Lombardy, recently obtained by the British Museum, is therefore of great interest, and it is now made available for science by a descriptive catalogue which has been prepared by Mr. James Brough. There is a varied series of new forms intermediate between the older and the later ganoid grades, and they are well illustrated by numerous outline sketches, restorations, and beautifully clear untouched photographs.

The essential changes in the bones of the cheek and in the median fins are especially traceable, and there seem to be all possible gradations. In fact, as Mr. Brough remarks, the ganoids of the later or 'Holostean' grade appear to have originated in several parallel lineages from the earlier or 'Chondrostean' grade. At first the preoperculum is a broad plate extending over the cheek above the long maxilla; it then gradually shrinks backwards until it forms merely the front rim of the gill cover, while the maxilla is reduced behind and is left comparatively free. At first the tail is completely heterocercal, but the upper lobe soon becomes extremely reduced or even disappears; and the dorsal and anal fins are made more efficient by the exact correlation of the dermal rays with their endoskeletal supports.

There are so many variants in this evolution that Mr. Brough classifies the new Middle Triassic fishes in seven families, and he suggests that they should be separated both from the Chondrostei and from the Holostei in an order Sub-Holostei. He also describes in detail two of the earliest holosteans of the family Eugnathidæ, and discusses the relationship of the Triassic bony fishes to those of later date. Mr. Brough's volume is much more than a museum catalogue, and he is to be congratulated on having formulated problems of wide biological and geological interest.

A. Smith Woodward.

SCIENTIFIC RESEARCH AND AGRICULTURE*

By Sir Thomas Middleton, K.C.I.E., K.B.E., C.B., F.R.S.

When, in 1912, Section M held its first meeting, my presidential address was upon the early improvers of husbandry, and I referred especially to the assistance given to agriculture through the societies and associations formed by them for promoting experiments and discussion. Section M was the latest addition to associations of the kind, and we who were then present looked forward with expectation to the benefit agricultural science would get from the formation of the new section. In spite of the calamity of the War of 1914–18 and the unrest in the world which has since developed, I feel sure that, in returning to Dundee where that first meeting was held twenty-seven years ago, all will agree that the hopes then formed have been more than fulfilled by the progress of Section M.

My purpose in selecting the motto "Practice with Science" is not to use it as an occasion for a review, but so that I may refer to matters affecting the present circumstances of both partners in the motto. The existence of Section M is in itself a proof of the large amount of scientific work now being carried out on behalf of agriculture, and also of the interest which the scientific public take in the subject. Although it has many shortcomings, as the workers concerned will be the first to admit, it may be claimed for agricultural science that it has prospered and is prospering; in contrast, everywhere there is evidence of the difficulties of agricultural practice.

With subsidies, price-insurance and other measures of the kind for assisting agriculture which at present occupy so much of the farmer's thoughts, the majority of scientific workers have no direct concern. The remedies for agriculture's handicaps which they have to offer depend on research, and fortunately research is a remedy so widely approved that, when it does arouse criticism, the complaint usually is that too little use is made of it and that the financial resources provided are too meagre.

For criticism of the kind there is, no doubt, justification; but in the past thirty years, scientific research in agriculture has made great progress in Great Britain, and the prospects for further progress are now better than they ever have been. The subjects under investigation at our research institutes and university departments of agriculture are so numerous that the time at my disposal would not permit me to comment on them in any adequate way. My remarks on the scientific workers' programmes must necessarily be of a very restricted kind.

As for meagre financial resources, no one can be more conscious of the needs and demands of the scientific worker than I am. During long years in Whitehall, I have many times reflected that the doctrines of Malthus, confounded though they may be by twentieth-century birth statistics, are peculiarly applicable to agricultural science; the pressure of its annual recruits on the means of subsistence has given me many an anxious hour. Yet when I look back to the first years of the century, when Hall, Russell, Percival and Theobald were breaking new ground at Wye, when Wood and Biffen were making the reputation of the Cambridge School of Agriculture, when Somerville had already shown how pasture improvement may be effected and measured, it is not the meagreness, but the growth of the resources now available to the agricultural worker that impress me. For I recall that, in the first report to be written by me in Whitehall Place, I had to point out that for the purpose of experimental work and research the State had granted no more than £380, whereas in the present year the Development Fund, which Mr. Lloyd George provided for us in 1909, is assisting the scientific worker in agriculture, and through him the British public, to the extent of some £500,000; and the Development Fund, although much the most important, is not the only source of funds available.

It is questionable if the general public realizes how largely the programmes of the agricultural investigator are framed in the interests of the nation as a whole. Indeed, if these programmes were framed solely for the farmer's benefit, some who have read my doleful account of the difficulties caused to the unhappy farmer by surfeited markets, may suppose that my remedy would be transference of the millstone of surplus from the shoulders of the producer to the neck of the scientific worker! But although fully conscious of the large increase in world production recently brought about as a result of the activities of plant breeders, chemists, pathologists and others, I trust you will not think my logic faulty if I disclaim any such idea.

---

* From Part II of the presidential address entitled "Practice with Science", Section M (Agriculture) of the British Association, delivered at Dundee on August 31.

Take, for example, the benefits that both agriculture and nutrition would derive from discoveries that would improve the health of farm livestock. By raising the standard of health in domestic animals we would meet some of the most insistent demands of nutrition experts. It is generally agreed that nothing would do more to reduce the number of C3's among us than an increase in the consumption of milk and eggs; it is generally claimed, too, that to secure increased consumption, prices must be less than they now are, and I believe it will be held by those who have studied costs of production that the possibility of lowering prices depends first and foremost on improving the health of the cow and the hen. So long as the wastage in dairy herds and poultry flocks remains at the present level, it is difficult to see how the cost of milk and eggs could be much reduced. To a less extent, perhaps, but still to a substantial degree, the cost of other animal products is increased by the ravages of disease on our flocks and herds.

It was the extent of these losses to the stock owner, and their effect on the food supply of the public, that led the Agricultural Research Council, soon after it was established in 1931 and had surveyed the tasks confronting it, to decide that its main effort in the immediate future should aim at effecting an improvement in the health of farm animals.

With this object in view the Council formed technical committees which brought together for joint study those already engaged in the investigation of a number of diseases of special importance. It made grants for assisting research in numerous cases where additional funds were necessary. It employed trained surveyors to visit stock-raising districts in which diseases, especially those of an obscure kind, were prevalent, and in this way collected much fresh information on the incidence of disease. Experience gained in work of the kind pointed to the need for a central field station at which it would be possible to carry out investigations on selected diseases on a large scale and under farm conditions. For this purpose the Council has acquired an estate of about 1,500 acres, and this is being provided with laboratories, houses for the breeding of laboratory animals and isolated cattle sheds for accommodating animals under investigation.

The work of the Council on animals is paralleled by the assistance it provides for investigational work on farm crops. Committees of specialist workers have been set up, for example, on virus diseases, on plant diseases due to helminth attack and on insecticides and fungicides. One very active committee has been that on the Preservation of Grass and other Fodder Crops. Most of the special grants made by the Council for work on crops are in aid of pathological investigations. Until 1911 very little attention was given to crop diseases in Great Britain, but when the Development Act provided funds, entomologists and mycologists were added to the staffs of most agricultural institutions and, as research workers or advisory officers, they have since given much-needed help to agriculture and horticulture; thus the increase in fruit growing and other forms of horticulture that has taken place in recent years has been stimulated by the researches of plant pathologists and, as in the case of animal products, the nutritional demands of the public are being successfully met because of the invaluable aid which the scientific worker is able to give to the producer. Some of the best examples of "Practice with Science" that the country can show to-day may be found in the orchards of Kent and other apple-growing counties.

So far I have referred to matters that engage the attention of the scientific worker, while agriculture follows what has been called 'its natural lines'; but unhappily for us, our peaceful art must face the problems raised by war, and although opinions have been expressed, and expressed freely on the subject in recent months, it cannot be said that there is any agreement on the role that agriculture either should, or could, be expected to fill in the event of war. Recent discussions, and my own experience in attempting to increase home produce during the War of 1914–18, lead me, therefore, now to refer to the scientific workers' programme in connexion with home food production.

In recent discussions on this subject, advocates of storage, of increased shipping for transport and of increased tillage for home production have all been heard, but too frequently as advocates of rival methods of providing supplies in war. It cannot be stated too strongly that these methods are in no sense rivals. All the aid that each can give would be wanted in a war of long duration. In the early stages of a war, stores would be of especial value, throughout the period of hostilities all the tonnage which could be made available for the carriage of human and animal foodstuffs would certainly be wanted, and in the later stages of a long war reliance might have to be placed largely on home supplies.

It may be accepted, I think, that in any emergency, while every effort would be made to maintain our normal diet, chief anxiety would be caused by the position of energy-supplying foods, in practice our breadstuffs. It was generally recognized during 1914–18 that the comparative absence of food difficulties then experienced was due to the circumstance that breadstuffs were not rationed.

In the pre-war years 1909–13 Great Britain was producing about 35 per cent of its energy requirements; in 1918 the food production campaign succeeded in raising the home supply to about 42 per cent. Entering the war with home supplies that would have maintained us for 125 days, we produced in 1918 the equivalent of 155 days' normal needs. Because of lack of labour, machinery and implements the difficulties we faced were extreme. With the number of tractors now available, grassland could be broken up rapidly; but it is one thing to break up grassland and quite another thing to farm it properly, and it is the farming, rather than the breaking up, that calls for careful preparatory work.

But why break up grassland? That was the question asked in 1915 and 1916; it caused much controversy and will do so again.

The answer is that, of human food of the kind which we should chiefly want in war, other crops produce much more than grass. In "Food Production in War" I have given many figures in support of this opinion which I need not cite here: one general statement will suffice. In the years 1909–13 the soils of the United Kingdom maintained a population of about 15½ millions. I estimated that less than one-third of this total had been maintained by our 34 million acres of cultivated grassland (that is, had been provided with the million Calories per person per annum necessary), and that more than two-thirds had been maintained by our 13 million acres under crops other than grass. Per 100 acres of land, 12 and 80 persons respectively had been provided for. These figures, though they relate to the energy value of foods only and not to other things which are essential in our diet, give a fairly correct idea of the relative importance of grass and other crops in providing war rations. The chief reason for the very low production shown by grass is that a large percentage of our grassland is of poor quality and is grazed by store cattle and sheep. For the average pasture grazed by dairy cows my figure was 41 persons maintained per 100 acres; well-managed grass carrying good cows might indeed provide the energy needs of 75–80 persons per 100 acres.

Our present systems of husbandry took form long before the aeroplane had to be reckoned with and they may be regarded as suitable for conditions that until recently existed, but I cannot agree that, as Europe now is, we should remain satisfied with methods of farming that, in war, would leave us dependent for some 65 per cent of our food supply on imports. My personal view is that, for defence reasons, we must change to a more flexible method of farming than that which is now commonly followed, that we should adopt a system which under peace conditions would provide from 35 to 40 per cent of our requirements and in an emergency would enable us rapidly to increase food production to a figure providing about half our annual needs. The change which, for defence reasons, I now advocate is that for which my predecessor argued at Cambridge on grounds of good farming, namely, a change over from permanent to temporary grass.

Sir George Stapledon advocated ley farming on an extensive scale. The adoption of this system would in his view improve the output of nearly all English cultivated grassland. For the purpose I suggest above, it would not be necessary to replace more than from four to five million acres of permanent grass by temporary leys. If, say, 4½ million acres were thus converted, Great Britain would then have 16½ million acres under arable cultivation as it had fifty years ago. About 40 per cent of the cultivated area would still remain under permanent grass, so that, in selecting the area for conversion into temporary leys, a wide choice would be available.

The substitution of temporary for permanent grass need not, in itself, call for substantial changes in the character of the land's output. The grassland would, as Sir George Stapledon stated, carry more stock, and if stock were paying better than crops the main change in output under peace conditions would be an increase in livestock products. From the point of view of war farming the advantages of temporary leys are obvious. The use of the plough and of other implements would be familiar to farmers cultivating temporary leys, but in many cases would be quite unfamiliar to those occupying only permanent grass. Tillage implements would be available on the farms on which they would be required in an emergency and the quality of the land itself for tillage purposes would be well known; thus, in an emergency, arrangements for corn growing could quickly and easily be made.

In spite of the advantages to both the country and the farmer which can be claimed for ley farming, it must be recognized that in England there are circumstances which strongly tend to check the spread of the system. Permanent grass growing is the well-established custom of the country; the change over from tillage to grass farming saved many from bankruptcy at the end of the nineteenth century, and since that time grazing has, on the whole, been a safer business than agriculture. Again, short of capital as farmers are, it would take a good deal of courage to expend £3 to £7 per acre in forming a temporary ley, even if arithmetic proved that a return of 10 to 20 per cent on the outlay may be expected over a period of years. The confidence of farmers in the future has been undermined as a result of their experiences since the War of 1914–18, and much will depend on the extent to which confidence can be restored as a result of the Government's recent policy.

What is now called for is intensive research at a central station on the many questions that would arise in connexion with the conversion of permanent into temporary grassland, together with a close study of local conditions, favourable and unfavourable, for the extension of ley farming, by economists and other scientific workers in different parts of the country. Sir George Stapledon himself is at some pains to explain that he is not an economist; all the more need that we should put the economist on his tracks! He has already persuaded a number of farmers to adopt his advice, and the results secured by men who have successfully turned from permanent to temporary grass farming would be of much value. Relatively the number of men concerned may be small, but I believe that they are sufficiently numerous to provide us with guidance of a kind that we cannot afford to neglect.

There are, indeed, features in the present situation which suggest that there is much scope for the economist, and not only in connexion with the interpretation of the experiences of grass growers. All readers of agricultural journals know that, in spite of agriculture's depressed state, there are within the industry many enterprising men who are doing well both for themselves and for their land. Their methods are certainly worth study and exposition, and the audience waits. Thanks to such movements as the Young Farmers' Clubs and to the facilities for training provided by Farm Institutes, there are now in Great Britain a large number of lads and young men keenly interested in agricultural progress and anxious to learn. Economic studies of the methods of successful men would be welcomed by these learners and by them would be translated into practice later on. The young farmers of my generation learned chiefly by example, and no doubt the young farmers of to-day continue to do so; but to-day, much more than formerly, they are so trained as to welcome precept, if precept is based on economic studies of the kind I have in view. Thus in the process of converting some four or five million acres now in permanent grass into temporary pastures, which would be necessary to fit England to respond rapidly, as Scotland already can, to the call for increased food supplies, I lay much stress on the assistance which the economist can give.

The awakening of the soil, which would follow the breaking up of permanent grassland, would intensify the programmes of most other scientific workers and in some cases would call for substantially increased activity. This would be the case especially in agricultural engineering. Whether in tilling a larger area in normal times, or in rapidly extending the tillage area in war, no form of aid would be more welcome to the farmer than aid in selecting and employing machines and implements that would enable him to use manual labour to advantage.

Many other matters would call for the attention of the scientific worker in war; some of them could be predicted because of 1914–18 experience, others could not, for one thing learned in 1914–18 was that war throws up new and unexpected problems. On the precise nature of these problems we need not now speculate; rather let us note that the scientific worker is confronted with one very definite objective. This objective, which must be approached from different angles, may, in a sentence, be stated to be the preparation of British agriculture to expand its normal output of food rapidly if called upon to do so. The immediate aim should be the provision of a six months' supply of food for the nation in an emergency.

Many of those who have considered the subject of food supply in war would not agree with the views I express; they would point to agricultural experience in recent years and argue that the production of half the nation's food from the soils of Great Britain would be impossible. But while I admit that experience since 1919 has not been encouraging, my view is that our present tendency is to underestimate the capacity of our agriculture, and I claim that our outlook should not be restricted by the experience of the past twenty years.

There is little amiss with the soils, or the climate, of Britain; our tillage land responded well to the calls made on it a century ago and would respond again. Our farmers taught those of most other countries, and if their pupils are now, in some cases, ahead of them, there is no lack of farming talent. Research and education in agriculture have been with us for a generation; growth may have been slow at first, but advances are now being made at a rate that is encouraging, and we may confidently expect much more aid from science in future than it has given us since 1919. Thus, from the technical point of view, I see no insuperable difficulties in the programme I have outlined.

From the point of view of farmers themselves, however, the case is otherwise. If they and their employees are to earn as meagre a share of the national income in future as they have done in the past twenty years, a further decline in the arable area is only too likely, for the reason that, under recent conditions, masters and men have lost confidence in their future prospects.

There is an atmosphere of 'defeatism' about, and not only among agriculturists themselves. There is too ready an acceptance of the doctrine that economic changes have condemned the land of England to slumber under grass, and that economic reasons forbid its awakening by the plough. As matters are, it would certainly cost the nation money to bring several millions of acres back into arable cultivation and to substitute temporary for permanent pastures; but if the change were made, not only would we add largely to the agricultural output, but also there is at least a prospect that farmers would find themselves better off than they now are. In my judgment the ease with which tolerably good grass can be grown in many parts of England has led far too many farmers to bury their talents under the green sod, and too many farmers, as well as their counsellors, believe that it is prudent to leave these talents buried; but looking to the future I am satisfied that good and faithful service to the country calls for a change, and, I hope, for a change that would be rewarded. To science I look for assistance in bringing this change about and, for the farmer's reward, to the belief that the world's non-agricultural inhabitants cannot expect a continuation of the conditions which, during the past century, have enabled them to buy their food at less than cost price. But these conditions may not quickly alter, while changes in farming are needed now, and as I have admitted that the nation must pay before large changes in our methods of cultivation can be expected, I will be asked: Why should the nation pay?

Whatever the next year or two may hold in store, Britain, hateful as the prospect may be, cannot afford to neglect preparations for defence. In these preparations agriculture must have a place. How large this place should be is a matter of opinion. My personal view, based on experience gained during 1914–18, is that it should have a large place; but be its place large or small, it is for services rendered in connexion with defence that farmers can legitimately ask the nation to pay, as it is paying, and paying heavily, for the services of others similarly engaged.

Thus looking to the future I conclude that the century-old motto which heads my paper is still applicable; the nation which relied on the British farmer for its food supply in 1839 cannot do without his aid in 1939; while he himself, if he is to do his part as his forefathers did, must take as his watchword "Practice with Science".

NUCLEAR REACTIONS IN STELLAR EVOLUTION*

By Prof. G. Gamow,

George Washington University, Washington, D.C.

(3). Apart from the stars of the main sequence, there is known a large class of stars having very high luminosities but possessing much lower effective temperatures (that is, much greater radii) than the stars of the main sequence of the same luminosities. In the Hertzsprung–Russell diagram these so-called *red giants* form a rather irregularly distributed group on the upper right side of the main sequence. Because of anomalously large radii these red giants possess very low densities, and the estimated central temperatures are considerably lower than those for the stars of the main sequence (for typical red giants the central densities can be as low as 5×10^{-7} gm./cm.^{3}, and central temperatures less than 1×10^6°C.). Thus it is clear at once that the energy production in these stars cannot be due to the same nuclear reaction as in the stars of the main sequence, and we have to look for reactions taking place at an appreciable rate at much lower temperatures than the carbon-nitrogen cycle. From Table I [p. 575] we see that the nuclei which can be responsible for the energy production at lower temperatures are the isotopes of heavy hydrogen, lithium, beryllium and boron, and, using the data of this table together with formula (1), it is easy to estimate at which temperatures these different processes will be of importance. Then, using the homology transformations, we can calculate the location of stars with different energy-producing reactions in the Hertzsprung–Russell diagram[8].

The result of such calculations shows that stars with different energy-producing reactions should be located within different rather broad bands running parallel to the main sequence. The central lines of these various bands are shown in Fig. 2 together with the central line of the main sequence. It is interesting to notice that, whereas the bands corresponding to the reactions of the isotopes of hydrogen and lithium are very close together, the bands of ^{10}B and ^{11}B are widely separated. This comes from the fact that the two isotopes of boron lead to quite different nuclear reactions, one being

* Continued from page 577.

the radiative capture and the other the much more probable splitting into three particles.

In order to notice this 'lateral structure' of the red-giant region, it is most convenient to use the observational material on the ***pulsating stars*** which, as well known, form a one-dimensional sequence, all their properties being the functions of their (directly observable) pulsation period. In Fig. 2 the region of pulsating stars is shown by a shaded area, its width at each point being proportional to the number of stars observed. We see that there are definite concentrations of stars near the places where the different thermo-nuclear reactions of light elements, calculated as indicated above, become of importance. The short-period group of cluster-variables contains the stars in which the transformations of ^{10}B probably take the main role. The second group includes the *Cepheid variables*, the number of which shows a broad and irregular distribution as a function of the period; this is probably due to overlapping of three separate groups corresponding to the reactions of $^{6;7}$Li, ^{9}Be and ^{11}B. Finally, the group of the ***long-period Mira-type variables*** should be interpreted as due to deuterium (and possibly ^{3}H). It can be seen that the calculated effective temperatures for the stars of this group are considerably higher than the values actually observed. It must be due, however, to the fact that these stars show abnormally high central condensations[9] and the observed effective temperature actually corresponds to the extremely rarified outer atmospheres surrounding the main body of the star.

The same kind of 'lateral structure' would be also expected for the non-pulsating red giants, and, as a matter of fact, something of this kind can be seen in the diagram, where all stars with known characteristics are plotted; however, due to large errors of the parallax measurements of these stars, the structure is not so definite as for the pulsating variables.

Inasmuch as the light elements responsible for the life of red giants do not possess regenerative properties like carbon and nitrogen, and are permanently destroyed in the process of energy production, the life-periods of a star during which the different reactions mentioned above are of importance are very short as compared with the time a star spends on the main sequence. As soon as one of the light elements is consumed, the star undergoes a comparatively much faster, gravitational contraction until the central temperature reaches the value suitable for the beginning of the reaction of the next element. The evolutionary track of such a star is shown by a heavy line in Fig. 2.

Now we come to the discussion of a very peculiar feature of the Hertzsprung–Russell diagram. It has already been pointed out that the pulsating variables are distributed along a definite line crossing various bands of the red-giant region. It is also known that this line represents ***an upper limit*** for the distribution of red giants, and that almost no stars are known between this line and the upper part of the main sequence. What is the physical meaning of this limiting line, and why do the stars begin to pulsate when they approach this line in the process of their evolution? The answer to this question can probably be found[10] by considering the relative importance of the production of thermo-nuclear and of gravitational energy in a red giant. If $-dX_1$ represent the decrease of the content of the light element responsible for the reaction, the total amount of the liberated energy will be evidently given by $Q.dX_1.M/m$, where M and m are the masses of the star and of the atom of the element in question and Q the energy liberation per nucleus. According to the homology transformations, the decrease of X_1 will cause a corresponding decrease of the radius of the star which, in its turn, will lead to the liberation of a certain amount of gravitational energy. The condition that this additional liberation of energy can be neglected as compared with the nuclear energy is evidently

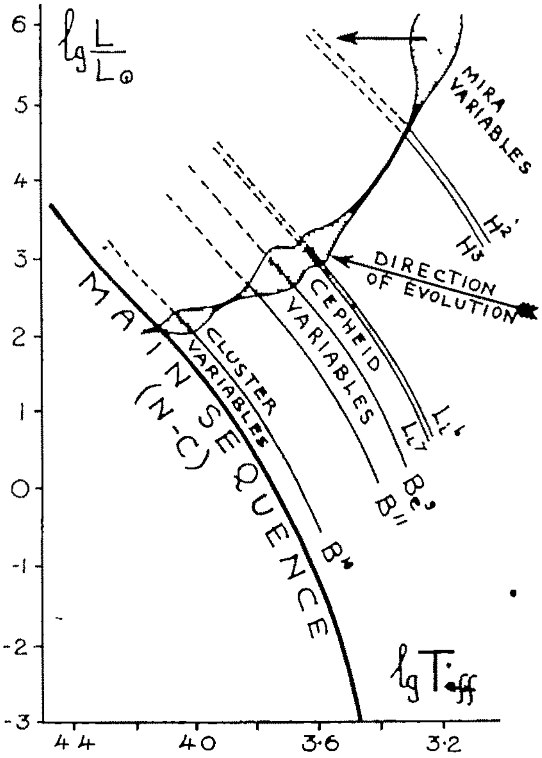

Fig. 2.

$$d\left(\frac{GM^2}{R}\right) < QdX_1\,\frac{M}{m_1}, \qquad (5)$$

which can also be written, using the homology relation between R and X, in the form:

$$\frac{R}{M} > \frac{1}{n + 1{\cdot}75}\,\frac{Gm_*}{QX_1}. \qquad (5^1)$$

Remembering that $M \sim L^{1/3}$ and $R \sim L^{1/2}\,T_{\text{eff.}}^{-2}$, we can write our condition for the critical line in the form: $L \sim T_{\text{eff.}}^{12}$, which roughly coincides with the equation of the line of pulsating variables. Moreover, substituting the numerical values, we find that the line given by this condition really passes through the location of these stars in the diagram. *Thus the line of the pulsating stars represents the geometrical locus of points where the gravitational contraction begins to play a more important part than the nuclear energy production.* Above this line no 'lateral' structure can be expected, and any star goes through this region rapidly contracting and radiating the gravitational energy liberated in such contraction. This process stops, however, as soon as the star reaches the main sequence where, due to a very high abundance of hydrogen, the energy liberation through the catalysing action of carbon and nitrogen becomes again the predominant process.

Let us now imagine a star which has just passed this limiting line and the source of energy of which is therefore mostly gravitational. If, for some reason, the radius of the star decreases slightly, the central temperature will increase correspondingly and the nuclear energy production will become of importance, giving to the star an impulse to expand. But as soon as the expansion starts and the central temperature again drops, the nuclear energy production becomes again negligible as compared with gravitation. It is easy to see that *this effect will cause an undamped pulsation*—in which the star will be, so to speak, 'bouncing on the critical line'. The pulsation will last as long as there is still sufficient amount of the reacting element, and there is every reason to believe that *the observed pulsations of stars near the limiting line are due to such a process.* After the amount of the element responsible for the pulsation becomes quite negligible, the star will rapidly pass the region of gravitational contraction and will become a star of the upper part of the main sequence.

(4). It remains now only to consider the later stages of stellar evolution, when the star, after staying sufficiently long in the main sequence, has consumed all its original content of hydrogen and enters into the stage of the final gravitational contraction. It is known[11] that the final stage of such contraction depends essentially on the mass of the star.

If the mass of the star is smaller than *the limiting value* 1·4 $M_\odot$ (for stars completely deprived of hydrogen), a degenerated electron gas will begin to be formed at a certain stage of contraction, and the star will tend to the state of very high density and low luminosity characteristic of the stars known at present as *white dwarfs.*

For stars of larger mass, no lower limit of contraction exists, because the gravitational pressure of the outer layers cannot be balanced at all by the pressure of the degenerated electron gas. At a certain stage of the contraction one may expect that *in the interior of the star a large amount of free neutrons will begin to be formed*, leading to a rapid collapse of the whole star and to the liberation of tremendous amounts of gravitational energy[12].

The question as to how such explosions can be connected with the observed phenomena of *novæ* and *supernovæ* is not yet quite clear, and we will not enter here into its discussion.

Summing up, we can say that, due to the application of our present knowledge of nuclear physics, the problem of stellar energy sources and the main features of stellar evolution can be considered at present as practically solved.

SUBSTITUTES FOR PETROL

THE need to conserve available supplies of petrol and the consequent severe restriction of the amount allotted under the rationing scheme in Great Britain, raises a question as to the applicability of other fuels to the ordinary motor-car or trade vehicle. It has to be borne in mind, however, that at the present time no fuels should be used except for good and sufficient reason, as fuel is a vital supply in the conduct of modern war.

The fact that town's gas was quite largely used in the years 1915–17 as a motor-car fuel suggests that it might once more be brought into service. It will be recalled that the cycle of operations in the petrol engine is essentially the same as that employed in the gas engine. In the former, the liquid fuel is atomized, metered and mixed with air by means of the carburetter, which also provides the means of controlling its flow. When gas is to be used, a diffuser of much simpler construction than the modern petrol carburetter can be employed, the mixture of fuel and air being effected by a gas supply pipe of about three eighths the diameter of the inlet pipe. On the gas supply pipe a regulating valve is necessary; this might be of the needle type and it might be arranged to operate in conjunction with the accelerator pedal. A main gas tap is obviously needed, because when the engine is shut down the gas must be turned off. For perfect combustion about 6 volumes of air must be supplied; but for economical results 8–10 volumes are better. The power obtainable will be somewhat less than from petrol, but there should be some saving in cost per mile.

For the storage of gas, large and cumbersome gas-bags were used, the obvious place for which is on the roof. As an alternative, steel cylinders containing high-pressure gas can be carried, but as these would generally have to be given some of the interior space of the car, their presence would doubtless be found less acceptable than the swaying bulk of the gas-bag overhead.

The use of gas is in the nature of a reversion to an older system; but it cannot be said that the newer systems offer any possibility of ready adaptation to existing cars. The heavy oils used in Diesel or semi-Diesel engines require a quite different cycle of operations and therefore an essentially different engine. The direct use of powdered fuel is making headway; but it would necessitate an engine approximating to the heavy-oil type. A further possibility is that of generating coal gas for the use of the engine; but this would involve the provision of extra plant as well as the adoption of a new technique by the driver.

The most immediately hopeful change-over will, therefore, be to the gas-bag, out of place as it may appear on a smart car. Some gas companies are understood to be planning the supply of gas in bags both at their works and through the garages and service stations, and it may be anticipated that they will arrange also for the provision of gas-carburetters or diffusers so that an easy change-over may be effected. The subject has received little attention in the text-books and reliable data are difficult to obtain. In "Carburetters and Fuel Systems" by A. W. Judge (third edition), illustrations of several carburetters will be found and quite a lot of practical information that would be most useful to anyone considering making this change.

OBITUARY

Mr. Sydney Evershed

MR. SYDNEY EVERSHED died on September 18, at the age of eighty-two years, at his home in Ealing. He had been associated with the manufacture of electrical testing instruments for fifty-three years. As an inventor his influence can be traced in the development of many electrical instruments in many countries in the world. He was the son of John Evershed of Gomshall, Surrey, and his younger brother John, the well-known astronomer, a fellow of the Royal Society, now resides at Ewhurst, Surrey.

At a meeting of the Institution of Electrical Engineers held in 1922 to commemorate the first ordinary meeting of the Society which was held fifty years previously, Mr. Evershed gave some interesting reminiscences of his own early life. In 1876, the year of the Centennial Exhibition in Philadelphia, he read in the newspaper of someone having listened to Hamlet's soliloquy being spoken by Dr. Graham Bell's telephone, and was lost in amazement, as at that time it was commonly believed that this would have required thousands of musical reeds. A year later he saw a drawing of a telephone and was surprised to find how simple its mechanism was. With the help of two baking-powder boxes in which he cut holes in the lids with his knife, a small bar magnet and some silk-covered wire wound round one pole, and a disk of thin sheet iron, which he cut with scissors, near the other, and using a long piece of telegraph wire to form the connecting line between the two crude telephones, he found to his amazement that they worked admirably, the speech transmitted being practically perfect.

He remembered in his own early life in Surrey the days when you saw only one arc lamp at a time, and what a great blaze of light it made to people accustomed to the dingy gas lights in the streets! In these days a strenuous research was being made 'to subdivide the electric light'. There was great excitement amongst the physicists when a cablegram came from America saying that Edison had succeeded in dividing it by means of a platinum incandescent lamp. Contemporaneously with this feverish research, Joseph Swan was working in England on his carbon vacuum lamp.

Evershed was then living a few miles from the town of Godalming in Surrey. Strange to say, this quiet Surrey village was the first town in England to light its streets by electricity. A dynamo was installed in Pullman's leather mills, not far from the town, on the river Wey, where water-power was available. The electric lighting of Godalming began on December 15, 1881. He remembered, on a later date, seeing the leather mills lit up with what he was told were Swan lamps. A leather worker with whom he spoke had a Swan lamp all to himself, but he admitted that he preferred a tallow candle. The main street of the town was illuminated by three arc lamps and the smaller streets by Swan lamps. The electric cables were simply laid in the gutter. He remembered kneeling on the pavement and putting a charm compass close to the cable and being very puzzled because he got no deflection. It was his first experiment with alternating current. In about a year afterwards Joseph Chamberlain's Electric Lighting Act was passed, and the newly born industry of electric supply was practically snuffed out for six years.

In 1886, taking with him samples of measuring instruments of a moving iron type which he had made with his own hands, Evershed applied for and obtained the position of manager of a little factory established by the firm of Goolden and Trotter in Westminster for the manufacture of Cardew hot-wire voltmeters, for which there was then a considerable demand in the Navy. Captain Philip Cardew had invented this instrument two years previously. It was the first of its kind and in many ways was most suitable for its purpose.

After several changes of name the firm became Evershed and Vignoles, Ltd., with Mr. Evershed and Mr. Vignoles as managing directors. In 1889 Mr. Evershed introduced his portable ohmmeter and hand generator. From this date the measurement of the insulation of house wiring ceased to be a laboratory operation. In 1903 he completed his invention of the moving-coil ohmmeter. He combined the high-voltage generator and ohmmeter in one box in such a way that there was no magnetic interference and the instrument called the 'megger' was in demand in practically every country in the world.

The firm built a large factory called 'Evershed and Vignoles' near Chiswick Park Station. In 1924 Evershed gave up his position as managing director but remained as chairman until he retired in 1938.

In 1931 Evershed was asked by the Council of the Institution of Electrical Engineers on the anniversary of the birthday of David Hughes to give a discourse on his life and work. He gave a most enlightening discourse, dwelling mainly on the two outstanding achievements of his life, namely, (1) the invention in his early years of the synchromonotype-printing telegraph and (2) in later life the discovery of the microphone. In reading this discourse you get a deep insight into the life and work of this great inventor. At the receiving end the message was printed on a paper ribbon by the action of an electromagnet in the circuit. Each time the contact arm at the sending end passed over a live stud, a current traversed the line and the electromagnet. The armature of the magnet forces the paper ribbon into momentary contact with the type-wheel and a letter is printed. Only one impulse was required for each letter.

Mr. Evershed's special knowledge of the magnetic properties of alloys of iron and of their use in instrument making greatly impressed scientific visitors when they came to meetings of the Institution and at Council dinners. He often spoke in discussions at the Institution of Electrical Engineers, where his humorous touches always pleased his audiences. The first time the writer heard him speak was in 1891 when J. Swinburne (now Sir James) read a paper on transformer distribution and W. Crookes was in the chair.

In 1899, G. Marconi read his classical paper on wireless telegraphy to the Institution of Electrical Engineers, Prof. Perry being in the chair. In this paper he mentions how he demonstrated the feasibility of signalling between Ballycastle and Rathlin Island in northern Ireland, the distance between the two positions being 7½ miles. Mr. Evershed, who spoke in the discussion, said that he had been working on telegraphy to lightships for many years. One of his suggestions which was submitted to a Royal Commission was tried and found to be a total failure. He therefore desired to be the first to congratulate Mr. Marconi very heartily on having succeeded. Evershed was always delighted and pleased with other people's discoveries.

In 1900 the writer remembers him reading a paper on a 'frictionless motor meter'. He forestalled criticism by pointing out that the adjective 'frictionless' was used in the comparative sense, just as we say 'smokeless' powder or a 'water-tight' compartment. The floating armature was magnetically suspended when working and its vertical axis was pivoted at the lower end.

In his early years Evershed investigated the phenomena exhibited by insulating materials when under electrical stress. His results are given in a paper read before the Institution of Electrical Engineers in 1913, and papers presented to the same Institution in 1930 and 1935 gave the results of his work on permanent magnets which yielded data that enabled scientific design to be substituted for rule-of-thumb methods.

Evershed was for several years a member of the Council and a vice-president of the Institution of Electrical Engineers. The writer knows also that he was invited on more than one occasion to be president. His portrait, painted by Mr. George Harcourt, R.A., was presented to him by his firm to commemorate his fifty years connexion with it. It is now in the keeping of the Institution of Electrical Engineers.

A. R.

We regret to announce the following deaths:

Prof. G. F. Arps, professor of psychology in the Ohio State University, on September 16, aged sixty-five years.

Prof. Henry C. Cowles, emeritus professor of botany in the University of Chicago, on September 12, aged seventy years.

Sir Spencer Lister, director of the South African Institute for Medical Research, known for his pioneer work on pneumococcal vaccines, on September 6, aged sixty-three years.

Prof. R. S. Troup, C.M.G., C.I.E., F.R.S., professor of forestry in the University of Oxford, director of the Imperial Forestry Institute during 1924–35, on October 1, aged sixty-four years.

NEWS AND VIEWS

Prof. M. von Laue

On October 9, Dr. Max von Laue, professor of theoretical physics in the University of Berlin, will be sixty years old, and we take the opportunity to congratulate him on his brilliant scientific work, and especially on his conception of the diffraction of X-rays by crystals, which has led to the development of more than one new and important branch of science. In 1912, Dr. von Laue made the fundamental suggestion that crystals, which had long been believed to contain a lattice structure regularly repeated in space, might behave towards X-rays as a diffraction grating behaves towards light. He worked out in some detail the diffraction effects to be expected from such a three-dimensional grating, and his suggestion led directly to the experimental discovery of the diffraction by his collaborators Friedrich and Knipping. The diffraction pattern obtained when a beam of X-rays of mixed wave-length falls on a crystal is now universally known by his name. The immediate effect of the discovery was to settle the contemporary discussion about the nature of X-rays. The work was immediately taken up by scientific men in all countries, including, of course, the Braggs in England, and, in the years that followed, the diffraction of X-rays has developed into our most powerful method for studying the structure of aggregated matter. Its significance for the biologist is, perhaps, only beginning now. In these days of international antagonism, it is well to note that the branch of science initiated by von Laue has developed by the co-operative effort of men of all nations. Dr. von Laue has numerous friends in Great Britain; all of them hope that he has yet many years of fruitful work before him.

The Central Register: Section for Scientific Research

The Royal Society, at Trinity College, Cambridge, has sent a communication in connexion with the Central Register to the heads of scientific departments in universities, firms, etc., who supplied the Royal Society with lists of persons recommended for the Register. It is pointed out that the Central Register is now being used by the Ministry of Labour for filling vacancies. Some classes are being absorbed rapidly, others only slowly. To obviate hardship, particularly in the latter, it is proposed, in the Scientific Research Section, to make an urgency list of persons who are now unemployed, or whose present jobs are coming or likely to come to an end. This list will be given to the Ministry and, where possible, vacancies will be filled from it. The original lists of recommendations for inclusion on the Register are being returned with the request that names of those who should be placed on such an urgency list should be specially marked. The Royal Society is aware that many scientific people anxiously await information as to whether and when use will be made of the offer of service implied in their registration. No general answer can be given. The absorption of scientific personnel is proceeding, but this is bound to take time, and there is no certainty that every volunteer can be used in his professional capacity. In view of future needs, many will be best advised to remain in their normal occupations for the present. It is permissible, however, to seek employment, with the defence services or otherwise, which is not inconsistent with the Schedule of Reserved Occupations. If doubt exists, the Ministry of Labour can consult the appropriate panel. If employment in national service is obtained otherwise than through the Central Register, the Ministry of Labour should be informed.

Scientific and Industrial Research in India

The report of the Industrial Research Bureau, Government of India, for the year 1938–39, covers work carried out on the development of Indian industrial research and industry by the Bureau, including that of the Industrial Research Council and of the Research Branch of the Government Test House, Calcutta. The Bureau itself has been responsible for work on casein plastics and has shown that high-grade rennet casein is required, while the resin at present produced in India is of the lactic acid type, which is inferior for this purpose. A modified technique for the preparation of rennet casein suitable for operation under Indian climatic conditions requires development by laboratory investigations. The Bureau has also examined the economic and technical possibilities of manufacturing both rayon and staple fibre in India by the viscose, as well as by the acetate, process. It has continued its co-operation with the Central Standards Office Railway Board in matters concerning the lubrication and painting of railway rolling stock. With the view of developing the manufacture in India of phenol and formaldehyde for use in synthetic resins for moulding powders, disinfectants, etc., arrangements have been made for investigations of crude tar acid and phenol-cresol products from the cold distillation plant in Bihar. The Indian Lac Research Institute at Ranchi has obtained promising results in developing a shellac-urea-formaldehyde moulding powder.

The Research Branch of the Government Test House, Calcutta, has continued its paint investigations, covering revised technique for the assessment of natural weathering of paint as well as accelerated weathering, and the investigation of paint formulæ. The setting of pigments and the dispersion and suspension of red lead pigments have also been investigated, including weathering tests with dispersing and suspending agents, which indicate that the use of aluminium stearate is in no way harmful. Studies of particle size have indicated that aluminium stearate reduces the particle size of the red lead pigment to a remarkable degree. Investigations of the growth of fungus on paint films on exposure to weather indicate that substances such as sodium silicofluoride, magnesium borate and tribromophenol, which have proved effective in Western countries for preventing fungus growth, are of very little value in Bengal, but mercuric oxide and mercuric phthalate appear to retard the growth of fungus perceptibly. Work on vegetable oils and lubricants included a search for more effective antioxidants for castor oil in presence of iron, as well as for ground nut oil and for cottonseed oil. The most effective antioxidants found so far for cottonseed oil are not quite effective enough, and the best antioxidants for ground nut oil are less effective than those found for castor oil. Attention is now being confined to castor oil and ground nut oil brands, for which purpose α-naphthol, α-naphthylamine and β-naphthylamine appear to be the most effective antioxidants. Other studies have covered the use of vegetable oils as diesel oils. Work carried on in connexion with the glass industry has covered the improvement of glass furnaces and accessories.

Delinquency and Psychology

IN the July issue of the *Quarterly Review*, Mr. Claud Mullins, the well-known Metropolitan Police Court magistrate, remarks that some believe that the discoveries of modern psychology completely rob our present methods of trial and punishment of all justification, and that nearly all who have committed any serious breach of the criminal law should pass into the hands of psychotherapists and thus be cured, while others deny that our present legal and penal methods are in any way affected by psychology. Both extreme opinions, however, are gradually diminishing. Psychotherapists, by closer contact with delinquents, have become more modest in their practical attitude, while magistrates and lawyers are beginning to realize that psychologists can be of assistance. Mr. Mullins himself has sent innumerable delinquents to psychotherapists, and in many cases has found the results satisfactory. It must, however, be borne in mind that psychologists are concerned mainly with an individual while the Bench is concerned also and mainly with society. Certain criminals, such as fraudulent financiers, fire-raisers, stealing postmen or railway servants, policemen who accept bribes and alcoholic motorists who kill or maim, cannot be dealt with solely or even mainly from the point of view of what is best for the delinquent, and in such cases severe punishment is required to discourage others. While regarding it as highly dangerous for the Bench to assume the functions of the psychotherapist, Mr. Mullins maintains that some knowledge of psychology and psychotherapy is desirable alike in the judge, recorder, stipendiary magistrate and lay justices.

Museums and Education

SIGNIFICANT of the new stress being laid upon the educational possibilities of museums was the presence of the President of the Board of Education, the Right Hon. Earl De La Warr, at the Jubilee Conference of the Museums Association, held at Cheltenham in July. In an address to the members the President of the Board gave clear evidence of his own interest in museums and indicated that, but for the special financial condition of Great Britain, he would have announced the setting up of an inquiry into the relationships of museums to education and to the State. On the whole, he seemed to be doubtful about the expediency of bringing the museums of the country under the control of the Board of Education, believing that freedom of initiative was greater under the present system, and that a happy combination of official help and collaboration with local or voluntary effort was a source of strength in many spheres of work in Great Britain.

THE same point from another angle was referred to in a subsequent discussion at the Conference by Mr. J. Wilkie, secretary to the Carnegie United Kingdom Trust. He pointed out that at present, so far as legislation goes, museums (other than national museums) are almost all linked with libraries and library authorities under the Public Libraries Acts of 1892 to 1919. But these Acts are adoptive, and there is no Government grant in aid of any service which is carried out under an adoptive Act. So that the Markham Report, in suggesting Government grants with some measure of control, is suggesting something quite revolutionary in library and museum policy—the substitution of a compulsory for a voluntary system. That was the problem which faced educational reformers in 1870, and it raises the question whether public opinion, as represented by the man in the street and the public authority, has reached that point of belief in the necessity of museums as educational institutions which would compel the museum service to be made comprehensive, universal and compulsory. Are compulsory museums to follow compulsory education ? An account of these discussions appears in the *Museums Journal* of September.

Anthropological Expedition to Brazil

A PRELIMINARY report, the first to appear, on the movements and work of the expedition to Matto Grosso, Brazil, of Dr. Levi-Strauss and Dr. J. A. Vellard, based on the infrequent telegraphic dispatches which had been received to the time of writing, has been published in the *J. de la Société des Américanistes*, N.S., 30, 1939. The expedition started from São Paulo in May 1938, and, proceeding along the line of the Rondon telegraphic system, made telegraph stations its bases for contacts with the Indians. At Utiarity, Juruena, Nhambiquaras, and Vilhena relations were established with various groups of the Nambikwara, of whom there are approximately 2,000 individuals in a territory extending 400 kilometres north of Utiarity. Three linguistic divisions were differentiated. The material culture was poor; but evidence was obtained of their social organization, system of relationships, family life, and of certain aspects of their technology and art. By October the expedition had arrived at Pimento Bueno, which was selected as a base for further research. Here visits were paid to groups belonging to Guaporé culture, but not classified linguistically. A prolonged stay in a village halfway between Presidente Hermes and Presidente Penna, of which the inhabitants were numerically poor and culturally degenerate, nevertheless proved fruitful in sociological material. Towards the end of the year, on reaching Presidente Penna, the return of the expedition by the normal route towards the south was barred by torrential rains and the ill-health of the members of the expedition. It was, therefore, decided to leave the country by the north in the direction of the Rio Madeira and then west to Bolivia.

Research on Lawns

INVESTIGATION of the particular ecological problems which relate to lawns began in America towards the end of last century. It was not until 1920, however, that such research was prosecuted on a national scale in that country, and not until 1925 that any adequate provision was made in Great Britain. The report for 1938 of the Board of Greenkeeping Research, St. Ives Research Station, Bingley, Yorks. (pp. 1–77, price 2*s*., July 1939) shows to what adequate development the investigation of greenkeeping matters has now attained. There are approximately 1,600 experimental plots at the Station, to inquire into the response of grass varieties to manurial and mechanical treatments, to control pests and diseases, and to select the most suitable varieties of grass for various purposes. Seed of the new strain of St. Ives Creeping Red Fescue is grown and distributed, whilst an improved strain of *Agrostis tenuis* should yield upon a small commercial scale in 1939. Experiments on the control of pearlwort and other weeds are in progress, the effects of sulphur as a dressing for heavy ground are being investigated, treatment of the soil with potassium permanganate for the control of earthworms has proved satisfactory, and various diseases of turf have also been studied. The Station now maintains an extensive permanent collection of greenkeeping implements, and has 'museum' plots of grass and weed species—features which are of great value to students who attend the two courses of instruction which are held during the year. Letters and advisory visits have reached higher maxima than in any previous year, and the results of the Station's researches are published in its *Journal* and in various reprint publications.

The Electric Battery Vehicle

ACCORDING to the *Electrical Times* of September 28, one result of the outbreak of war is a considerable increase in the number of inquiries received by manufacturers of electric accumulators and vehicles as to the price of their wares, the charges of electricity required by the vehicles and the distance traversed for a given charge on a smooth road. Petrol rationing has compelled owners of motor-vehicles to curtail seriously their usual transport facilities, and they are considering the relative advantages of petrol and electricity for transport. Since electric vehicles take their power from storage batteries they are designed as a rule to have only a moderate range of action, varying from about 25 to 45 miles per charge of the batteries. The distance depends on the number of stops that have to be made. If the number of stops are numerous and the average time of a stop long, the advantage lies greatly on the side of the electric vehicle, since it only takes power when it is running. Most retail deliveries are carried out on a 'customer convenience' basis and not on 'transport economy basis'. It has been estimated that the petrol ration for C licence holders is only sufficient for their vans and lorries to cover half the normal mileage. If they have been doing about 75 miles per day, then they would be able to substitute an electric vehicle and still be in the same position as at present. For any distance between 35 and 75 miles per day, an electric vehicle would be an excellent substitute for a petrol one. The electric vehicle has other advantages. It has a long life; low maintenance and cheap running costs enable it, for many duties, to prove superior to alternative transport methods. In addition, it has the advantage of being exceptionally clean, free from fumes and simple to operate. A one-ton carrying capacity petrol van running 10,000 miles a year will use about 650 gallons of petrol, whereas the electric will use 4,000 units of electricity, or about 3 tons of coal. Owing to the grid, if at any time difficulties in transport should arise, then those power stations involving the minimum amount of coal transport could take over much of the load.

Properties and Testing of Heat-Insulating Materials

A GENERAL discussion on "The Properties and Testing of Heat-Insulating Materials", organized by the Joint Committee on Materials and their Testing, in conjunction with the Institution of Gas Engineers, will be held in London on November 23. Authorities from Great Britain, the United States, France, and Canada are to take part. Further particulars can be obtained from the Secretary, Joint Committee on Materials and their Testing, Institution of Mechanical Engineers, Storey's Gate, London, S.W.1.

Chemical Society

THE Chemical Society will continue to function at Burlington House, London, unless circumstances render it impracticable to do so. It is the intention of the Council to publish the *Journal of the Chemical Society* each month as heretofore and to issue the "Annual Reports on the Progress of Chemistry, 1939" in the early spring of 1940. *British Chemical and Physiological Abstracts* "A", *Pure Chemistry*, will also continue to be published monthly. The Council has accepted, with great regret as from September 30 the resignation of Prof. J. W. Cook from the office of honorary secretary, on his appointment to the regius chair of chemistry of the University of Glasgow. It has expressed its high appreciation of the eminent services Prof. Cook has rendered to the Society during his term of office. Prof. W. Wardlaw, professor of physical chemistry in Birkbeck College, London, has been appointed by the Council to fill the vacancy until the next annual general meeting. The programme of lectures, discussions and meetings of the Society for the reading of papers, arranged for the session 1939–1940, will inevitably suffer drastic alterations. The Council hopes, however, that modified programmes will be carried out, and particulars of meetings will be announced from time to time. Until further notice the Society's Library will be open each weekday from 10 a.m. to 1 p.m., and from 2 p.m. to 5 p.m. or sunset when earlier, except on Saturdays, when the hours will be from 10 a.m. to 1 p.m. The Research Fund Committee will meet early in November to consider applications for grants for research purposes. These must be received by November 1.

Physical Society

A special meeting of the Council of the Physical Society was held on Friday, September 22, to discuss the Society's activities in the immediate future. It was decided that the science meetings, the annual exhibition of scientific instruments and apparatus and the annual competition in craftsmanship and draughtsmanship should be suspended for the present, but that the publication of the *Proceedings* should be continued as usual. Volume 6 of the Society's annual "Reports on Progress in Physics" is now in the printers' hands, and it is hoped that this volume will be issued at the usual time—the end of the present year. The Council recently had under consideration a project to hold local meetings of the members of the teaching and research staffs of the physics and related departments of a number of the provincial universities and university colleges; normally two such meetings would have been held in each session in the physics departments of two of the universities concerned. The officers and Council hope that, even though this scheme may not be carried out in its entirety, it may still be possible for local groups to hold meetings of an informal type under the auspices of the Society. For the present, the business of the Society will be carried on at its office at 1 Lowther Gardens, Exhibition Road, London, S.W.7 (Telephone: Kensington 0048); all communications and the MSS. of papers submitted for publication by the Society should be sent to the honorary secretaries at that address.

Institution of Civil Engineers

It is announced that the Council of the Institution of Civil Engineers has decided to continue, so far as may be practicable, the work of the Institution from the headquarters building in Great George Street, Westminster, S.W.1. The meetings of the Institution in London will be suspended until further notice, and the Conference on Engineering Education and Training and the Road Engineering Exhibition are postponed indefinitely. The October examinations of the Institution will be held in London, but not in the provinces. The Council will continue to co-operate in the work of the Central Register of the Ministry of Labour and to assist the War Office and other Service Departments in the recruitment of qualified civil engineers for posts in which their professional experience is of value.

Royal Institution

The policy to be followed by the Royal Institution during the War has been under consideration by the managers, who have decided to maintain its normal activities so far as possible. The libraries and reading rooms will be kept open as usual. Although the present 'black-out' restrictions prohibit the holding of the Friday evening meetings, a series of afternoon lectures at an earlier hour is being arranged and will be announced in due course.

Royal Society

The Royal Society will function normally during the war; the administrative office is located in Trinity College, Cambridge, and it is probable that the meetings of the Society will be held in that town.

Institution of Professional Civil Servants

The Institution of Professional Civil Servants has temporary headquarters at 20 Cedar Road, Sutton, Surrey, to which communications should be sent.

Announcements

Mr. W. C. Wilson, director of the unit for Clinical Research in Surgery at Edinburgh Royal Infirmary, has been appointed regius professor of surgery in the University of Edinburgh.

Prof. Kwanichi Terazawa, dean of the Faculty of Science of Tokyo Imperial University, has succeeded Prof. Mishio Ishimoto as director of the Earthquake Research Institute. Prof. Ishimoto will continue his researches as a member of the Institute.

Dr. Gerald B. Webb, research director of the Colorado Foundation for Research in Tuberculosis, has recently been awarded the Trudeau Medal of the National Tuberculosis Association in recognition of his attempts to produce specific immunity against tuberculosis by the inoculation of animals with very minute doses of tubercle bacilli.

Consequent upon the outbreak of war, the celebration of the Royal Microscopical Society's centenary this month is postponed, and a further notification will be issued in due course.

It was announced in Nature of September 30, p. 592, that the Imperial College is preparing to re-open most of its departments at South Kensington on October 10. We are asked to state that the date is not yet fixed and that students will be advised when to return.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 637.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Connexion between the Life-time of the Meson and the Beta-Decay of Light Elements

As is well known, the assumption of the instability of the meson, which is included in the fundamental hypotheses of Yukawa's theory of beta-disintegration, has received a striking qualitative confirmation from investigations of the absorption of the penetrating component of the cosmic radiation[1]. As stressed by Nordheim[2], there is, however, in the forms of the theory successively considered by Yukawa[3] a serious quantitative discrepancy regarding the value of the ratio between the life-times of the free meson and of *light* beta-radioactive elements: the value of this ratio, calculated by using the values of the constants determined from the magnitude of the nuclear forces, turns out to be much smaller than that derived from observation. Since this discrepancy affects equally any other form of the theory involving only one of the four types of meson fields which, according to Kemmer[4], are possible *a priori*, it may be concluded that no such form of the theory will be able to account quantitatively for the connexion between the life-time of the mesons and the beta-decay of light elements.

On the other hand, it is immediately apparent that the discrepancy in question can be removed as soon as a mixture of independent meson fields is introduced. Consider, for example, such a mixture of two fields A and B. The additive contribution of the field B to the beta-decay constant may then for some elements be much larger than that of the field A, while the life-time of the free mesons associated with field B will be so short compared with that of the mesons associated with field A that only the latter would have been observed at present in cosmic radiation.

Now a discussion of the problem of nuclear forces[5] seems to bring out the necessity of introducing just such a mixture of two types of meson fields, namely, a vector meson field and a pseudoscalar meson field. A closer investigation, which is being continued, shows that such meson fields give rise to an interaction between heavy and light particles which, besides a term of the same type as that assumed in the original Fermi theory of beta-decay, may involve several possible combinations of other terms of a more complicated form.

The resulting theory of beta-decay thus contains a certain amount of arbitrariness, which a comparison with the available experiments is not yet able to remove. Anyhow, it may be expected that it will enable us not only to avoid the discrepancy pointed out by Nordheim, but also to account for such considerable variations of the form of the beta-spectrum and the value of the beta-decay constant from element to element, as are already indicated by the present empirical data.

A New Technique for the Spreading of Proteins and the 'Spreading Number'

The ordinary volatile solvents employed for fatty substances cannot be used for the spreading of protein monolayers on the surface of water, since the majority of proteins are soluble only in water. Hughes and Rideal[1] have spread proteins directly from the dry crystal, the amount spread being determined with a microbalance. Gorter and Grendel[2] deliberately inject an aqueous solution of the protein on the surface without worrying about the possible disappearance of a part of it in the substrate. Fatty substances and the exceptional protein, gliadin, have been successfully spread from alcoholic solution, in spite of the fact that ethyl alcohol is soluble in water. It appears that in this case, owing to its large spreading pressure, the alcohol spreads very rapidly before it has time to diffuse into the substrate.

Starting from these facts, a general method has been evolved for the spreading of proteins from aqueous solutions. The protein is dissolved in water, the surface tension of which is artificially lowered by adding traces of a capillary active substance, so that, when a drop is placed on the surface of the substrate, it quickly spreads. Once scattered, only the protein remains on the surface and the solvent dissolves in the substrate. As capillary active substance, amyl alcohol at a dilution of 1–2 per thousand has given very satisfactory results. The action is simply one of mechanical dispersion, and the same result may be obtained by using esters (for example, butyl acetate or propionate) as capillary active substances.

Various types of proteins have been thus spread on the surface of either distilled water or dilute hydrochloric acid or caustic soda. Particularly some globulins (for example, myosin, amandin, edestin) have been spread which were reputed not to form films, or at least to spread only on very concentrated salt solutions. Below are given the areas in sq.m. per mgm. occupied by these different globulins. These figures are simply intended to show how the surface concentrations are comparable with those found for the ordinary proteins.

Areas in sq. metre per mgm. under 1 dyne/cm.

	Myosin	Amandin	Edestin
Dist. water	0·9	0·9	0 7
HCl *N*/1,000	1·1	1·3	0·9
HCl *N*/100	1·6	1·1	1·3

A substance may have a very low spreading pressure and yet be spread and give a film stable under relatively high pressures. It has to be emphasized that, with substances that do not spread spontaneously, one of the functions of the solvent is to disperse the molecules over the largest possible area. It is found that to obtain complete scattering, it is necessary to ensure that the concentration of the protein in the drop should be below a certain quantity, just as is the case with solutions of stearic acid or tristearin in a volatile solvent and gliadin in alcoholic solution[3].

The 'spreading number'. It has often been noticed that the spreading of a protein from a crystal is more difficult, if not impossible (for example, casein), at the isoelectric point. This is to be expected since at that point the solubility is at the minimum and, therefore, the work of adhesion being also a minimum, the spreading pressure is lower. This variation of the spreading pressure with the *p*H seems to be in contradiction with the results of Gorter and collaborators, who found a maximum of the 'spreading number' at the isoelectric point, when the protein was injected as a solution. The contradiction is only apparent and is due to the bad definition of 'spreading'. The point in question is rather the *spreading efficiency*: Gorter's curves showing the 'spreading number' as a function of the *p*H or the salt concentration are three-dimensional solubility curves and do not represent a surface phenomenon. In reality, if the substrate's *p*H corresponds to the isoelectric point of the protein, this, being at its minimum solubility, will spread before an appreciable quantity has time to dissolve. At other *p*H or salt concentrations, it will be more or less soluble and the surface concentration will correspond only to the part of the protein which is left on the surface.

In order to show that the variation of the 'spreading number' with the *p*H is in any case not a surface phenomenon, experiments have been made in which the *p*H of the substrate was changed under the monolayer, after this had been formed and the state of equilibrium reached[4]. A layer of egg albumin was spread by the Gorter and Grendel technique on *p*H 4·9 (*M*/1,000 acetate buffer). The *p*H of the substrate was afterwards brought successively to *p*H 3·2, 5·1, 2·6, then back to 4·9 and 11. The order of succession is immaterial: in one case, the film was spread on *p*H 7·8 (*M*/1,000 Co_3HNa) with the new technique and the *p*H afterwards brought to 4·9. The observed areas under 1·5 dyne/cm. are given below, the value 100 being arbitrarily attributed to the area at *p*H 4·9.

Egg albumin (relative areas under 1·5 dyne/cm.)

*p*H		*p*H	
4·9	100		
3 2	106		
5·1	100	7 8	97
2·6	108	4 9	100
4 9	100		
11	109		

If Gorter's curve represents the change of area occupied by a given quantity of egg albumin, the passage from *p*H 4·9 to 3·2 would have reduced the area to one eighth. Likewise, the film should extend 20 or 30 times by changing the *p*H from 7·8 to 4·9. Whereas in fact, as can be seen by the numbers above, the maximum variation in the area is at the most 10 per cent and the area is not even at a maximum at the isoelectric point. As noted by Philippi[5], a study of the complete isotherm shows that these relatively small variations in the area are entirely attributable to changes of the compressibility.

A more detailed account will be published elsewhere.

Comparison of the Adsorption, Electrolytic, and Interference Methods of Measuring Film Areas

THE Bowden-Rideal[1] electrolytic method of measuring area by the electrodeposition of hydrogen ions on conducting surfaces has been modified so that rapid measurements may be made by using audio-frequency alternating currents superposed on very feeble direct currents, and measuring directly the alternating changes of electrode potential with an amplifier and wave analyser with one megohm input impedance. Comparisons of surface areas were made by measuring the alternating current required to give the same alternating electrode potential as on one square centimetre of a mercury surface.

Measurements of the same surface were also made by the interference method[2].

Finally, the adsorption of palmitic acid was studied on large metallic granules with activated metallic surfaces, and when covered with coloured oxide films. The electrolytic method was also used with these granules. The results of adsorption measurements are near those of the interference method for slightly oxidized surfaces, but approach the order of magnitude of the electrolytic method for metallic surfaces.

A full account of the work will be published later.

Apparent Anomalous Isotopic Effect in Some Bands Associated with the Swan Bands

A NUMBER of weak bands have been noted in sources of carbon molecular spectra by Johnson[1] and by Fox and Herzberg[2]. Because of their association with carbon spectra, these bands were attributed to the carbon molecule, and several of the stronger ones (λλ 4770, 4836, 4911, 4997) tentatively identified as tail-bands of the Swan system. Measurements of the isotopic heads of the first three of these bands obtained from carbon enriched in the heavy isotope give some information concerning their nature and display an anomalously large isotopic shift.

The following positions of the heads of these bands were obtained from spectra of carbon containing 35 per cent ^{13}C, taken on a 21-ft. grating spectrograph in the first order. The source was an end-on quartz capillary discharge in argon containing a trace of methane, activated by a 3 kw. transformer.

^{13}C head	^{12}C head	Isotopic shift
4770·21 A. 20,957·60 cm.$^{-1}$	4764·77 A. 20,981·52 cm.$^{-1}$	23·92 cm.$^{-1}$
4836·16 20,671·80	4827·57 20,708·59	36·79
4910·95 20,356·99	4898·92 20,406·98	49·99

The values 23·92 cm.$^{-1}$ and 36·79 cm.$^{-1}$ are thought to be accurate to less than 0·1 cm.$^{-1}$, while the value 49·99 cm.$^{-1}$ is not so accurate because the band λ 4911 is much weaker than the other two.

The fact that only two heads were present, even in low dispersion spectra of carbon which contained 50 per cent ^{13}C, is clear proof that the emitting molecule is not C–C, but contains only one carbon atom. The isotopic shift is very large, and can be explained only by the unreasonable assumptions of an infinitely heavy emitting molecule, so that the carbon has its maximum effect on the vibrational energy, combined with very large correction terms for the effects of anharmonicity and rotational shifts. The origin of the band system computed from the relative magnitudes of the isotopic shifts is near 21,500 cm.$^{-1}$, so that the 0,0 band is probably covered up by the 1,0 (λ 4737) Swan band.

From the occurrence of these bands in a wide variety of sources of carbon spectra, they must be due to carbon combined with a very persistent impurity; and from their occurrence in sources of high excitation, the emitting molecule should not be very complex.

These bands were noticed incidentally to measurement of the ^{13}C spin, and on account of pressure of other work, no further research on them can be done at this laboratory.

Diffraction of Ultra-Short Radio Waves

SOMMERFELD[1] has shown that in the study of the diffraction of electromagnetic waves at a sharp edge, account must be taken of the contribution to the diffracted field of the wave which is reflected at the edge. Because of the variation in boundary conditions at the edge for radiation linearly polarized in different planes, Sommerfeld deduced that the shadow cast by a sharp edge should be deepest for radiation polarized with the electric vector parallel to the edge.

Wien[2] and Jentzsch[3], amongst others, have observed this feature for waves in the visible spectrum. We have obtained the same result with ultra-short radio waves in the wave-band 2–3 metres. When such waves are propagated over hills with long ridge formations such as are found among the downs of south England, we have noted that the shadow behind the ridges is always appreciably deeper for horizontally polarized (electric vector horizontal) than for vertically polarized waves. Typical results obtained on a wave-length of 3 metres on Dunstable Downs are given in the accompanying table. For a fixed transmitter position situated on a plateau about 200 yards from the edge of a slope some 400 ft. in overall height, measurements of the vertical and horizontal electric field-strengths were made at a series of positions on the slope, the transmitting aerial being oriented according to the type of polarization under observation at the receiver.

Position	Field-strength in microvolts per metre		Ratio: vertical/horizontal fields	Remarks
	Vertical polarization	Horizontal polarization		
1	4500	4000	1·12	Gradual slope
2	2200	1800	1·22	
3	1000	800	1·25	
4	630	400	1·57	
5	320	180	1·78	
6	125	70	1·79	Steep slope
7	80	28	2·86	
8	36	16	2·25	
9	32	12	2·67	Gradual slope
10	40	14	2·86	
11	40	17	2·35	

It will be noted that near the top of the ridge (position 1) the vertical and horizontal electric field-strengths were approximately equal, but that on moving the receiver down the hill into the shadow, the vertical electric field increased relative to the horizontal electric field, and that finally, as the slope lessened, both fields increased slightly but the vertical electric field remained throughout greater than the horizontal field.

Similar results have been obtained on other hills devoid of trees. The presence of trees complicates the propagation characteristics of ultra-short radio waves, but it has been found that in the wave-band 2–3 metres, vertically polarized radiation appears, in general, to be the most efficient for conditions in which diffraction by hills is predominant.

This work forms part of the programme of the Radio Research Board, and this note is published by permission of the Department of Scientific and Industrial Research.

Isotope Effect in Potassium Dihydrogen Phosphate

When the hydrogen in potassium dihydrogen phosphate (KH_2PO_4) is replaced by deuterium by repeated crystallization from warm 99·6 per cent heavy water (D_2O), the potassium phosphate separates in a different crystal structure. It can with some difficulty also be made to crystallize in the tetragonal form described by West[1], by adding a nucleus of KH_2PO_4 to a supersaturated solution of KD_2PO_4. When the new crystal form is powdered, it slowly reverts to the tetragonal form over a period of days.

As is being described elsewhere, a comparison of the tetragonal forms of KH_2PO_4 and KD_2PO_4 shows that the short hydrogen bonds (2·55 A.) are associated with a very considerable expansion of the lattice on substituting deuterium, thus showing similarity with the short hydrogen bonds in oxalic acid dihydrate and sodium bicarbonate[2].

The separation of acid potassium phosphate in a new crystal structure from heavy water is further evidence of the difference between hydrogen and deuterium bonds in crystals. So far as can be ascertained with the limited amount of material at present available, the new form is chemically identical with tetragonal KD_2PO_4 and has approximately the same density. From the X-ray data the crystals are monoclinic, with 8 molecules per unit cell, the axes being: $a = 7 \cdot 37 \pm 0 \cdot 01$ A.; $b = 14 \cdot 73 \pm 0 \cdot 01$ A.; $c = 7 \cdot 17 \pm 0 \cdot 01$ A.; $\beta = 92 \cdot 0^\circ$.

Random errors are as given. Systematic errors probably do not exceed 1 per cent except for the a axis, for the determination of which only weak reflections were available. The crystals tend to elongate along the c axis, and prominent faces are (100), (010), and (110).

A detailed investigation of the new crystal structure is being attempted, since it promises to throw further light on the role of hydrogen bonds in crystals.

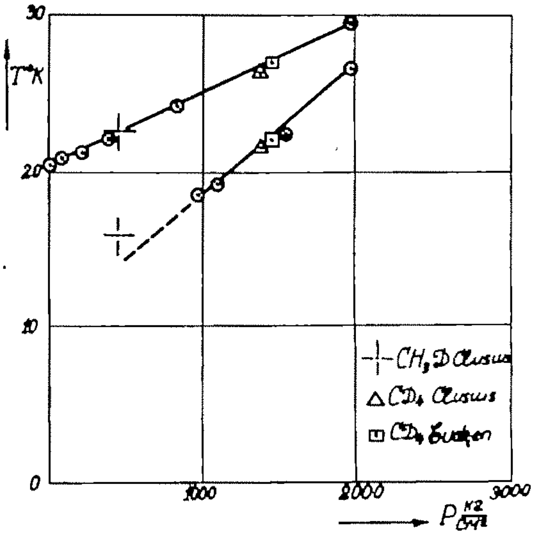
Specific Heat of Methane Under Pressure

Clusius[1] discovered the anomaly of the specific heat of solid methane at 20·4° K.; Eucken, Heuse and others showed further that there was a case of the so-called λ-point. It appeared desirable to study the influence of the pressure of transformation at the λ-point.

Clusius and Perlick investigated the specific heat of solid methane under pressure up to 200 kgm./cm.^{2}. In our laboratory the measurements of the specific heat of methane were carried out from 12° K. to 30° K. at pressures up to 2,000 kgm./cm.^{2}, and the preliminary results are reported below.

The measurements were performed in a steel calorimeter, the specific heat of which was 20 per cent of that of solid methane at 18° K. The pressure was transmitted by helium. At a pressure of 1 kgm./cm.^{2} the anomaly of specific heat occurred at 20·6° K. The maximum value measured was 200 cal./mol. (81 cal./mol. measured by Clusius), the breadth of the maximum at 10 cal./mol. was 0·4° (0·9° measured by Clusius). These data attest the high degree of purity of the methane investigated. The measurements at all pressures were effected with one condensation.

The measurements of methane under pressure revealed the existence of two maxima of specific heat which shift with changing pressure. The accompanying diagram represents the dependence of the temperature T of these maxima on the pressure P. From the curves it follows that the low-temperature maximum which appears under pressure is shifted by the pressure faster than the normal maximum.



To all appearance methane under normal pressure has the second specific heat maximum at the temperature of liquid helium. The pressure shifts this maximum to the region of higher temperatures, where it is observed as the second maximum. The displacement of the maxima appears to depend on the increase of the density of the substance caused by pressure.

Clusius and his co-workers discovered two specific heat maxima: at 15·5° K. and 22·6° K. in CH_3D and 21·4° K. and 26° K. in CD_4. The introduction of one molecule of heavy hydrogen (D) is evidently equivalent to the influence of pressure upon ordinary methane.

The same conclusions were drawn by Eucken and his co-workers from their investigations of mixtures CH_4 and CD_4. Extrapolating, these authors come to the conclusion that CH_4 under a pressure of 1,200 kgm./cm.^{2} must be equivalent to CD_4 at 1 kgm./cm.^{2}. Our measurements (see diagram) show the equivalency of CH_4 at 1,410 kgm./cm.^{2} to the CD_4 of Eucken. The CD_4 of Clusius is equivalent to our CH_4 at 1,350 kgm./cm.^{2}. This slight difference is probably due to the difference in the purity.

An examination of these results confirms the view expressed above as to the analogy of the augmentation of density of CH_4 by pressure and the substitution of D for H in the molecule.

These results have been obtained in a calorimeter in which the helium transmitting the pressure was in direct contact with the methane.

Colour of Celestine

Some months ago, through the good offices of Mr. B. Topley, of Messrs. Albright and Wilson, Oldbury, we obtained several specimens of celestine from near Yate, Glos. Some were colourless, others tinged with blue, whilst a few were red. The blue crystals have been observed locally to occur lining channels or 'pipes' where water has bored through the massive mineral; the particular conditions favouring the red crystals are not apparently known.

The blue colour, to which celestine owes its name, is usually attributed to traces of vivianite, which possesses deep pigmentary power[1]. This, however, can scarcely explain the red colour.

Doelter[2] attributed the colours of celestine and numerous other minerals to the presence of colloidal inclusions, the degree of dispersion of which would determine the colour, whilst the concentration would determine the depth of that colour. He suggested, further, that the blue colour of celestine might be caused by colloidal sulphur produced by reduction of some of the sulphate.

Spectrograms of our specimens showed that whilst only minute traces of iron were present, the characteristic lines of gold were well defined in the red and blue specimens, but were scarcely perceptible in the white. The gold was extracted with aqua regia, reduced with phenyl hydrazine[3] and weighed on a sintered glass funnel using a microbalance. The iron was determined colorimetrically.

The results were as follows:

	Gold (p.p.m.)	Iron (p.p m.)
Colourless crystals ..	nil*	19
Pale blue ,, ..	49	4
Deep red ,, ..	85	4

* Too small to extract.

It is noteworthy that the iron content was greatest in the colourless crystals, whilst the gold content rose with the depth of colour. When gently heated, the blue crystals became slightly pink, but the other crystals were unchanged.

We are inclined to the opinion, therefore, that the colours of our specimens are due to colloidal gold. We should like to examine specimens from other localities but are experiencing great difficulty in obtaining them; perhaps some readers of Nature could help to obtain specimens.

Vitamin B_1 and Acetate Oxidation by Bacteria

It is now known[1] that vitamin B_1 may be a necessary factor for the growth of bacteria. Bacteria can, however, be grown with minimal amounts of vitamin B_1 and such bacteria (for example, *Staphylococcus aureus*) may show enhanced metabolic activities so far as the breakdown of pyruvic acid is concerned, when the vitamin is added to suspensions of the washed cells[2]. If the bacteria are grown on a medium containing adequate quantities of vitamin B_1, the subsequent addition of the vitamin to the washed cells does not affect their metabolic changes. It is evident that a study of the action of vitamin B_1 on the chemical changes brought about by vitamin B_1-deficient bacteria may throw new light on the mechanism of action of this vitamin.

So far, attention has been mainly concerned with the effects of vitamin B_1 on pyruvic acid and lactic acid breakdown, following the work of Peters and his colleagues on the effects of this vitamin on the metabolism of avitaminous pigeon brain.

Werkman and his colleagues[3] have found that the growth and metabolism of propionic acid bacteria are affected by the presence of vitamin B_1.

We have found, using a washed suspension of propionic acid bacteria grown on a vitamin B_1-deficient medium, that the addition of the vitamin very markedly stimulates the oxidation of acetic acid.

Acetic acid is already known from the work of Stone, Wood and Werkman[4] to act as a hydrogen donator in the presence of the resting cells of propionic acid bacteria.

A typical result illustrating the action of vitamin B_1 on acetate oxidation is shown by the following figures, obtained with a suspension of bacteria grown on a vitamin B_1-deficient medium and incubated aerobically in a phosphate medium (in a Barcroft differential respiratory apparatus) at 37° for two hours:

Substance added to bacterial suspension	μl oxygen consumed	μl oxygen consumed, due to the acetate	μl acetate utilized
No addition .. .	197	—	—
0·25 γ vitamin B_1 ..	245	—	—
0 01 M acetate ..	563	366	193
0·25 γ vitamin B_1 + 0·01 M acetate ..	1202	957	486

The following conclusions may be drawn. (1) In the presence of very small quantities of vitamin B_1 (for example, $0{\cdot}08 \times 10^{-6}$ mgm. per ml.) there is a very marked stimulation of the oxygen uptake in the presence of acetate, though not in the absence of the added substrate. This stimulation is not due to an increase in the number of bacteria during the course of the experiment as cell counts have shown. (2) The ratio of oxygen uptake to acetate utilized is approximately 2·0 and this ratio appears to be independent of the addition of vitamin B_1. The ratio of 2·0 would be expected if complete oxidation of acetate occurred according to the following equation

$$CH_3.COOH + 2O_2 = 2CO_2 + 2H_2O,$$

and estimations of carbon dioxide (or bicarbonate) formation have been consistent with this conclusion.

It would be a plausible view that the catalytic action of the vitamin is due to its accelerative effect on the oxidation of pyruvic acid possibly formed as an intermediate during the oxidation of acetic acid. Against this view, however, is the experimental fact that no pyruvic acid appears to accumulate when the acetate is oxidized by the bacteria in the absence of the added vitamin. Moreover, a ratio considerably less than 2·0 would be expected if acetate were oxidized in the absence of vitamin B_1 to an intermediate the further oxidation of which required the presence of the vitamin. Experiment has failed to show that traces of pyruvic acid block the aerobic oxidation of acetic acid. The inference would be that the acetic acid molecule itself, in the case at any rate of propionic acid bacteria, requires the presence of vitamin B_1 to accomplish its aerobic oxidation. Whether this is the case with mammalian tissues is a matter shortly to be investigated.

Our experiments indicate that the catalytic agent is cocarboxylase (vitamin B_1 pyrophosphate) rather than vitamin B_1 itself (*cf.* Lipmann[5]). Silverman and Werkman[6] have recently shown that propionic acid bacteria are capable of synthesizing cocarboxylase from vitamin B_1.

More complete details of these and related experiments will be published in due course.

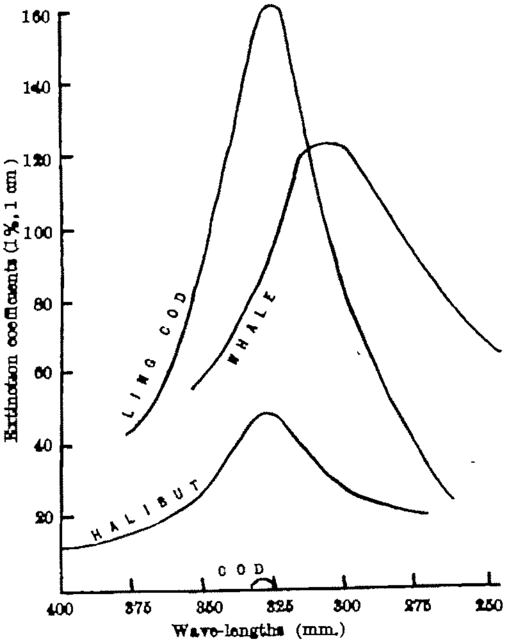
Vitamin A in Ling Cod Liver Oil

The ling cod, *Ophiodon elongatus*, is an interesting fish because (1) it is neither a ling nor a cod; (2) it is found only in the north-eastern Pacific Ocean, and is one of the chief fish catches in British Columbia; and (3) it yields a liver oil rich in vitamin A[1].

Recently, in a routine examination of fish oils for whale oil adulteration, no published absorption curves for ling cod liver oil, or for Pacific whale oil, could be found. Such curves, together with average halibut and cod, are therefore presented in this note.



Ling cod liver oil is seen to have a typical absorption around 328 mμ (vitamin A), and in this case, to be much more potent than the sample of halibut liver oil.

Whale oil adulteration can easily be detected by the criteria of Drummond[2], though the curve for whale oil shown here is not quite identical with his curves.

We are very grateful to Dr. H. N. Brocklesby, of Prince Rupert, B.C., who observed the high vitamin A content of ling cod oil, for a sample of liver oil from carefully identified ling cod, and for the whale liver oil.

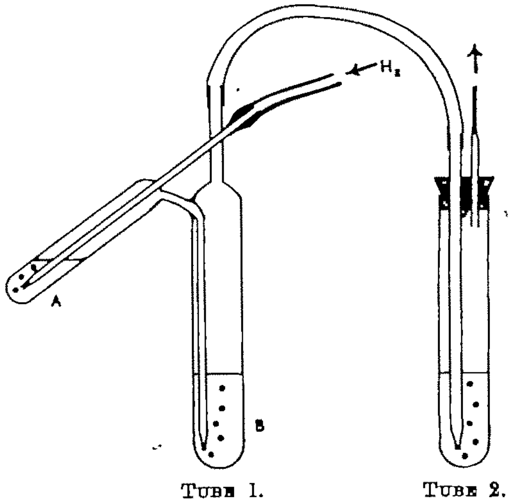
Decomposition of Hydrogen Peroxide by Catalase

It has recently been stated[1], and it appears to be generally accepted, that the decomposition of hydrogen peroxide by catalase can only take place in the presence of molecular oxygen. It has been pointed out, however[2], that this phenomenon is difficult to understand, since it would be expected that such a strong oxidant as hydrogen peroxide would certainly react with the reduced form of the enzyme according to the scheme proposed[1]. As this point is of fundamental importance in relation to the mechanism of cellular oxidations in general, we have carried out some critical experiments to test the validity of the hypothesis. Our results have furnished rather unequivocal evidence that the hypothesis is untenable, and we would, therefore, like to report them here.



The apparatus used is shown in the accompanying diagram. Five c.c. of a 0·1 per cent solution of hydrogen peroxide in 0·125 *M* phosphate buffer, *p*H 7·3, and 0·25 *M* sodium chloride were introduced into the rear arm (*A*) of tube 1, which was then connected by lead tubing to a heavy glass tube containing palladium asbestos. The glass to lead connexions were sealed with de Khotinsky cement.

Into the front arm (*B*) of tube 1, and also into tube 2, were introduced 25 c.c. of a suspension of luminous bacteria (*Ph. Fischeri*) in phosphate buffer sodium chloride solution. The outlet of tube 1 was connected to the inlet of tube 2 by a heavy rubber tube. The outlet of the latter consisted of a capillary tube inserted in the rubber stopper as shown in the diagram. With this arrangement, hydrogen purified over heated palladium asbestos was passed in a continuous stream through the two arms of the first tube, and thence through the second. In less than two minutes after starting the flow of gas, the luminescence in both bacterial suspensions dimmed, which, according to Shapiro[3], would indicate that the oxygen tension was already less than 0·14 per cent. In another five minutes, the luminescence was extinguished, to the completely dark-adapted eye, in tube 1, while remaining faintly visible in tube 2, showing the presence of a minute amount of oxygen that may have been dissolved in, or diffused through, the rubber connexion between the two tubes. The fact that there was no luminescence in tube 1 proves that certainly less than a 10^{-6} atmosphere[4] of molecular oxygen was coming into that suspension from the rear arm containing the hydrogen peroxide solution. After another ten minutes of passing pure hydrogen through the vessels it may be safely assumed that tube 1 was completely free of molecular oxygen.

Tube 1 was then tilted, so that the hydrogen peroxide solution from arm (*A*) was mixed with the bacterial suspension in arm (*B*). There was an immediate and bright flash of luminescence, and a few seconds later the suspension in tube 2 also lighted up. While it may be possible that the luminescence in tube 1 resulted from a direct oxidation by hydrogen peroxide, it is quite certain, from the luminescence appearing in tube 2, that molecular oxygen was liberated when the hydrogen peroxide solution was brought into the suspension of bacteria, and it is equally certain that this reaction began under completely anaerobic conditions.

To make certain that these results were due entirely to enzyme action, a portion of the same suspension was boiled for ten minutes and the experiment was repeated with boiled bacteria in tube 1. In this case tube 2 did not light up after the hydrogen peroxide was mixed with the boiled bacteria.

In connexion with the same experiments, it is interesting to note that the catalase activity of these bacteria, unlike the phenomenon of luminescence, is not dependent on intact, viable cells. Another portion of the same suspension was centrifuged and resuspended in distilled water, which immediately cytolyses the cells and extinguished both luminescence and respiration[5]. A drop of this suspension produced no growth on an agar slant, although the control, inoculated from the uncytolysed cells, produced abundant growth and bright luminescence.

Following the same procedure, hydrogen peroxide was again added in the absence of molecular oxygen. Tube 2 lighted up fully as well as it had when the living cells were employed in tube 1.

In conclusion, we would like to direct attention to the fairly well known, but frequently neglected, usefulness of luminous bacteria as a means of detecting the presence of molecular oxygen. May we suggest, also, that the simple method described in this letter might be profitably employed to investigate the activity of catalase not only in various species of bacteria but in enzyme preparations as well.

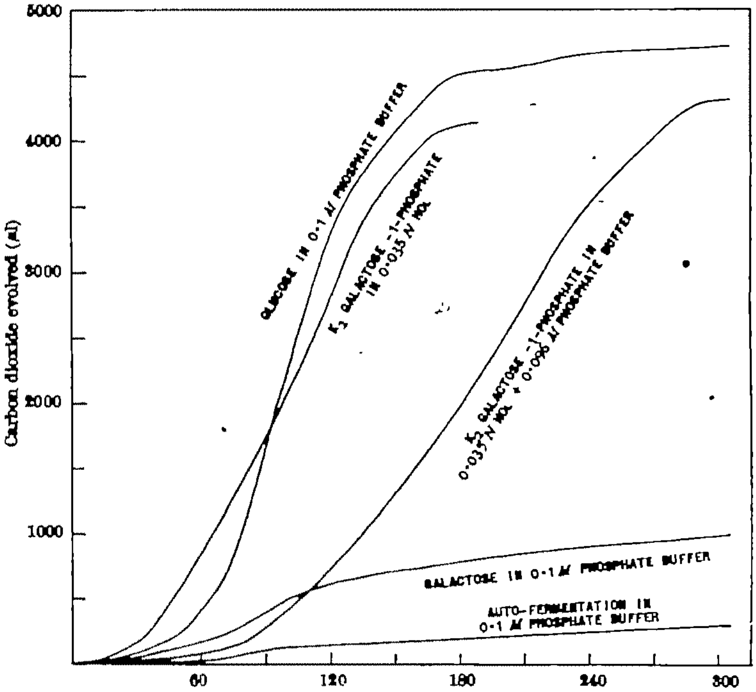
Galactose-1-Phosphoric Acid in Galactose Metabolism

The synthesis of α (?)-galactose-1-phosphoric acid has provided a means of examining the constitution of the galactosephosphate accumulating in the liver during galactose assimilation[1]. Both natural and synthetic esters are non-reducing, very readily hydrolysed by acid, and resistant to alkaline hydrolysis. After removal of the reducing esters by alkaline hydrolysis, the mixture of phosphoric esters



100 mgm. dried galactose-adapted *S. cerevisiae* Frohberg were used to ferment 1 mol of 0·1 *M* sugar or ester solution (*p*H 6·5). Readings were taken at intervals of 5–10 minutes.

isolated from the liver during galactose assimilation contained, apart from water of hydration, 29·6 per cent anhydrous barium galactose-1-phosphate, 3·1 per cent anhydrous glucose-1-phosphate, 2 per cent barium salt of an unidentified acid-labile ester, and 60 per cent barium salt of an acid-resistant ester. This mixture of barium salts had $[\alpha]_{5461}$ + 34·4° and the barium salt of the acid-resistant ester $[\alpha]_{5461}$ − 3·4°. Cori, Colowick and Cori[2] found for anhydrous barium glucose-1-phosphate $[\alpha]_D$ + 75° which corresponds to $[\alpha]_{5461}$ + 89°. By calculation from these values, natural barium galactose-1-phosphate would have $[\alpha]_{5461}$ + 114° while the corresponding value of the synthetic ester is + 110°. Determined in a similar manner, the constant of hydrolysis of the natural ester in 0·25 *N* HCl at 25° would be $0{\cdot}87 \times 10^{-3}$ while that of the synthetic ester is $0{\cdot}89 \times 10^{-3}$. These findings, together with the earlier evidence, make it highly probable that the galactosephosphate present in the liver during galactose assimilation is identical with synthetic α(?)-galactose-1-phosphoric acid. An attempt is being made to crystallize the natural ester as the dipotassium salt.

The biological significance of these results is emphasized by the fact that synthetic galactose-1-phosphoric acid is fermented by dried galactose-adapted *S. cerevisiae* Frohberg at approximately the same rate as is glucose, while galactose itself is fermented only very slowly (see graph). The relative quantities of carbon dioxide evolved during fermentation of glucose, of galactose-1-phosphoric acid, and of galactose, while subject to slight variation with change in concentration of inorganic phosphate, were 100, 94 and 15 respectively. It seems clear that in the fermentation of galactose, at least by the yeast preparation here employed, phosphorylation in position 1 is a necessary initial reaction proceeding at a relatively slow rate, while the phosphorylated product is fermented very rapidly.

The metabolism of galactose in the liver differs from fermentation by dried yeast in that galactose-1-phosphoric acid accumulates in the liver. The magnitude of this accumulation has not as yet been determined. There are obviously large losses in isolating the ester, which so far has been obtained in quantities equivalent to 5–12 mgm. of galactose per 100 gm. of liver.

Blood Clearance of Free Chloral in Normal and Liver-damaged Dogs

FOLLOWING up the investigation on the urinary elimination of administered chloral hydrate in normal and liver-damaged dogs[1], we have made further observations on the blood clearance of free chloral under more or less identical experimental conditions. The data collected are rather interesting and appear to us to be worth recording, in as much as the results not only substantiate our previous conclusions drawn from urinary experiments, but also point the way to the development of a comparatively quicker and possibly more sensitive 'blood test' for gauging the detoxicating efficiency of the liver.

After the oral administration of chloral hydrate to dogs, in doses ranging from 100 mgm.–200 mgm./kgm., 1·0 c.c. samples of blood were taken from the hind limb veins, the first sample being collected when a fair degree of somnolence supervened in the experimental animals (usually between 35 min. and 50 min. after chloral hydrate). Subsequent samples were collected at one-hour intervals for six hours in order to ascertain the time at which the maximum concentration of free chloral was attained in the blood. Free chloral was estimated by the pyridine colour reaction of Friedman and Calderone[2]. Curiously enough, normal blood samples of dogs were found to give a faint pyridine colour reaction. Unless this is taken into account in expressing the final result, a higher figure is likely to be recorded. To eliminate this possible source of error, it was necessary to take an initial reading of the normal blood sample prior to the administration of chloral hydrate. Again, the pyridine colour tends to fade away within a very short time. For accurate readings, it is desirable to finish the colour measurements within a minute after the solution has been finally diluted with water. When these precautions are strictly attended to, fairly reliable results are obtained.

A typical set of experimental results obtained at the height of free chloral concentration in the blood about forty-five minutes after oral administration is presented in the table below.

	Dog No.	Maximum concentration of free chloral in blood (mgm. per cent)		
		Dose of chloral hydrate administered orally :		
		100 mgm./kgm.	150 mgm /kgm.	200 mgm./kgm.
Normal animals	1 (6·3 kgm.)	1·32	2·30	3·50
	4 (6·3 kgm.)	1·54	2·25	3·14
	6 (6·4 kgm.)	1·10	2·00	3·32
* Recent liver damage	1	2·00	3·00	4·56
	4	2·00	3·32	4·00
	6	1·83	3·00	5·00
* Long-standing liver damage	1	3·46	5·00	9·00
	4	3·64	4·85	7·50

* Recent liver damage caused by 4–5 administrations of CCl_4, and long standing liver damage caused by 15–20 administrations of CCl_4; each administration = 2 c.c./kgm.

It will be noticed that there is a significant increase in the blood concentration of free chloral in liver-damaged animals with as low a dose as 100 mgm./kgm. of chloral hydrate. In cases of chronic liver damage, a well-marked change in free chloral concentration is usually observed. In recently induced liver damage, the difference, though not as marked, is sufficiently significant to warrant the conclusion that a differential diagnosis may be possible.

We are indebted to Prof. R. N. Chopra for constant advice and guidance.

Order of Magnitude of Morphogenetic Forces

The experimental analysis of embryonic development has been mainly concerned with elucidating the chemical mechanisms which cause different parts of the egg to develop into the organs and tissues of which the adult is composed. Much less is known about the physical forces which cause the changes in relative position which are such an important part of the developmental process. Preliminary measurements were therefore made of some of the physical magnitudes associated with the process of gastrulation in the eggs of the newt *Triton alpestris*.

In the first set of experiments, small steel balls were placed in the blastocoel cavity of young gastrulæ, and subjected to the magnetic field produced by one pole of a long bar magnet. The pole and the egg were gradually brought closer together until the ball was pulled through the blastocoel roof. Two sets of experiments were made: in the first, with a ball 0·216 mm. in diameter, breakage of the roof occurred at distances of 0·83, 2·0, 1·83, 1·0, 1·33, 1·0, 1·0 mm., average 1·36; in the second, with a ball 0·3 mm. in diameter, breakage occurred at 1·5, 1·5, 1·83, 1·5, 1·33, 2·0, 1·83, average 1·66. Converting these measurements into mgm. of pressure per sq. mm. of the hemispherical surface of the ball in contact with the roof, the averages for the two series are 7·02 and 7·29 mgm./mm.^{2}.

In another series of experiments, balls were placed among the gastrulating cells in such a way that the applied magnetic force was opposed to their normal movements; the eggs were placed at various distances from the magnet, and it was noted whether any movement of the balls took place over a period of about eight hours. For balls of diameter about 0·083 mm. placed in the mesoderm, movement occurred at distances of 9·5, 8·0, 6·83 (?), 6·66, 6·33, 6·0, 5·83 mm., no movement at 7·83, 5·5, 5·3, 5·16, 4·66, 4·0. For similar balls in the endoderm, movement occurred at 8·5, 5·83, not at 7·16, 6·0, 5·5, 5·0, 4·66, 3·83, 3·66, 3·33 mm. If we take for both tissues the limit at which movement could occur at about 5·66 mm., the maximum force exerted by the gastrulating tissues is equivalent to 0·34 mgm./mm.^{2} of the hemispherical surface.

These measurements are of a preliminary nature, and no great accuracy is claimed for them. It is interesting to note that the force exerted by the gastrulating cells is much less than the breaking strain of the tissue. Before any attempt can be made to interpret this it will be necessary to know something of the rigidity, and the viscosity at various rates of flow, of the tissues concerned.

Zoological Laboratory,
Cambridge. August 30.

Points from Foregoing Letters

The quantitative discrepancy between the observed and the theoretical ratio of the life-time of the free meson to that of a light radioactive element can be removed, according to C. Møller, L. Rosenfeld and S. Rozental, by combining a vector and a pseudoscalar field for the meson in the calculations.

D. Dervichian finds that when a protein is dissolved in water to which a trace of a capillary active substance able to lower the surface tension is added, the protein can be spread on the surface of an aqueous solution. He also discusses the meaning of 'spreading number'.

C. H. Townes discusses the presence, in the spectrum of carbon containing ^{13}C, of bands, hitherto ascribed to the carbon molecule, which he believes are due to a persistent impurity of complex molecular structure.

It has been found by J. S. McPetrie and J. A. Saxton that in the ultra-short radio wave-band 2–3 metres the attenuation of received field-strength for positions within the shadow of hills is most pronounced for radiation polarized with the electric vector horizontal.

A. R. Ubbelohde and Miss I. Woodward find that when deuterium replaces hydrogen in potassium dihydrogen phosphate, this substance crystallizes in a new structure, thus giving further evidence of the difference between hydrogen and deuterium bonds in crystals.

O. N. Trapeznikowa and G. A. Miljutin find two maxima, which shift with pressure, in the specific heat of methane between 12° K. and 30° K., at pressures up to 2000 kgm./cm.^{2}. The effect of substituting deuterium for hydrogen in methane has a similar effect to increasing the pressure on ordinary methane.

Specimens of blue and red celestine from Yate, Glos., have been examined by J. N. Friend and J. P. Allchin, who attribute the colour to colloidal gold.

J. H. Quastel and D. M. Webley find that the oxidation of acetic acid by suspensions of propionic acid bacteria grown on a vitamin B_1-deficient medium is greatly accelerated by the addition of small quantities of the vitamin, complete oxidation of the acetic acid taking place.

The statement has recently been made that the decomposition of hydrogen peroxide by catalase can only take place in the presence of molecular oxygen. F. H. Johnson and K. L. van Schouwenburg describe an experiment in which decomposition occurred under completely anærobic conditions.

H. W. Kosterlitz discusses the role of galactose-1-phosphoric acid as an intermediary in the metabolism of galactose in liver and in yeast. This ester is fermented by dried galactose-adapted *S. cerevisiæ* Frohberg about six times as rapidly as is galactose. There is an appreciable accumulation of the ester in the liver during galactose assimilation.

B. Mukerji and R. Ghose report that in recently induced and long-standing liver damage, a significant increase in free chloral concentration of blood occurs within an hour of the oral administration of chloral hydrate to dogs. Blood clearance of free chloral may, therefore, be employed as a test for detoxication function of the liver.

C. H. Waddington describes measurements of morphogenetic forces made by means of steel balls embedded in gastrulæ of *Triton alpestris* and then subjected to magnetic forces. The breaking strain of the blastocoel roof was of the order of 7·15 mgm. per sq. mm. of the hemispherical surface of the ball in contact with the tissues. Gastrulating mesoderm and endoderm could move the balls against a maximum force of 0·34 mgm./sq. mm.

RESEARCH ITEMS

Ethnography of the Washo of Nevada, U.S.A.

Robert H. Lowie, during a stay of several weeks at Minden, Nevada, and at Coleville, California, in 1926, was able to supplement the somewhat exiguous technical information available concerning the Washo. This is an isolated stock or an aberrant Hokan group ranged about Lake Tahoe in westernmost Nevada and easternmost California (*Univ. California Pub. Amer. Ethnol. and Archæol.*, 36, 5; 1939). Kroeber sets their number in 1770 as possibly 1,500, where more recent figures approximate 300. Their settlements were minute, their huts usually being from two to four. The chief had nothing to do with fighting enemies or adjusting quarrels within the tribe. His sole function was to arrange dances and other gatherings, where he would exhort the Washo to be good. Special headmen led in hunting jack rabbits, deer and antelope respectively. The antelope headman dreamed the right to office, the two others were purely secular leaders, the rabbit chief being chosen by the people. Property rights were maintained for clumps of pine nut trees, patches being marked off by lines of rocks. While brothers never quarrelled over pine nut privileges, trespass by a stranger was resented. Acorns were not a staple of diet, though the Washo made a dish of them. The pine nuts were gathered by men and women co-operatively. When dried, the nuts kept for about a year. Along the Walker River, the Washo constructed many 'fish houses'. Trout were speared and fish were also taken in nets or clubbed to death. Antelope, deer and jack rabbits were hunted communally. Other species of animal added to the food supply; porcupine, grasshoppers and locusts were eaten. The shamans became such through dreams, but not every dream was interpreted as a transfer of supernatural power, even though it might be of an uncanny character.

Sacred Twinned Vessels

M. D. W. Jeffreys describes and figures in *Man* of September a collection of sacred twinned vessels, now in the Wellcome Historical Medical Museum, London, which he obtained in 1930 in the markets of the native towns of Akwa and Aguleri, Nigeria—strongholds of the Umundri culture in the Onitsha Province. Design and decoration of one of the vessels suggest that the pottery is based on a wood technique. From the religious use to which they are put the vessels may be regarded as a unit combining the Patten and the Chalice. In them is placed the sacrificial food and oblation of wine when offered to a sky god *Chuku*, to *Alushi*, and to the ancestral spirits *Ndichie*. The vessels are not common, and with the increasing spread of Christianity are now seldom made. Similar twin vessels have been reported from Egypt. It is possible there is a connexion between the use of sacred twin vessels and the derivation of the word *graal* or *grail*. One suggestion is that *graal* is an abbreviation of *gradalis*—*grad*-'step' or 'division', *alis*-'food', that is, a combined or stepped vessel for keeping separate the sacrificial offerings. Bread and wine have been through the ages the offerings to the gods and ancestors and it is reasonable to assume special vessels to prepare and carry them, combining the two into a single unit. The use of vessels having separate compartments for different kinds of offerings appears in the Greek *kernos*, several small cups or jars joined together. It was used in the Eleusinian Mysteries to carry first-fruits, and a similar vessel of metal is in use in the Orthodox Greek Church to-day.

Arthritis in Wild Mammals

Herbert Fox, of Pennsylvania, in the course of examination of 1,700 wild mammals has observed changes in the joints which correspond with chronic arthritis in man (*Trans. Amer. Phil. Soc.*, N.S., 31, 75; 1939). This applies to truly wild animals as well as to menagerie specimens. The cases described seem to indicate that there is no apparent relationship between the incidence of arthritis and the systematic position, geographical distribution, habits or habitat of the mammals involved. On the whole the most conspicuous lesions occur among anthropoid apes, baboons, Felidæ, Hyænidæ, Ursidæ, Cervidæ and a few others; whereas a number of groups, such as Canidæ, Rodentia and Chiroptera, seem to be free from the disease, at any rate so far as shown by the material examined. Prof. Fox makes an interesting suggestion, that the one character which separates arthritic mammals from non-arthritics is body size. This may be compounded of a large body upon slender supports (as in Bovidæ), or stockily built body upon stouter supports (as in Felidæ). Where the greatest stabilization of the spinal column is demanded for the animal's locomotion there the greatest degree of spondylitis arises, and the localization of lesions in the fore-limbs of carnivorous mammals and the hind-limbs of herbivores may be associated with jolt-shock and locomotive power.

Deep-Sea Fishes of Bermuda

The importance of an account of the Bermudan deep-sea fishes of the family Melanostomiatidæ, by Walter Beebe and Jocelyn Crane, can be gauged from the size of the collection described. Intensive collecting in a limited area eight miles in diameter and a mile deep yielded 250 specimens belonging to 10 genera and 32 species, or 62 per cent of all known genera and at least a third of the species taken in all seas (*Zoologia*, 24, 65; 1939). The collecting was noteworthy also because extensive use was made of the bathysphere for recording movements and behaviour, and ten individuals, representing five species, were examined alive and their luminescence and behaviour noted, while more than 100 freshly caught specimens were used for the recording of colour notes and sketches. Hitherto only eight specimens in the entire family had been studied when freshly caught or recently preserved. As with most families of Bermudan deep-sea fish, the depths at which these were taken were greater than the average in other regions, practically none except very young individuals having been taken above 500 fathoms, although they were seen above that level from the bathysphere. The description of the collection runs to 174 pages and contains many striking figures of these deep-sea forms and their remarkable barbels.

Hymenopterous Parasites of Hover Flies

The hover flies or Syrphidæ constitute one of the largest families of the Diptera. In their larval stages many of them are highly beneficial to man since they prey upon aphides and thereby destroy very large numbers of the latter. They are, perhaps, the most important of all the natural enemies of these pests. The usefulness of syrphid larvæ is apparently counteracted to a considerable extent by species of hymenopterous parasites. Our knowledge of the structure and biology of such parasites is extremely meagre and their earlier stages have scarcely been observed at all. An attempt towards filling this hiatus in entomological knowledge is made by M. Kamal who, under the title of "Biological Studies on some Hymenopterous Parasites of Aphidophagous Syrphidæ", contributes an article as Bulletin 207 (Entom. Section) Technical and Scientific Service, Egyptian Ministry of Agriculture. The investigations embodied in this paper were carried out at Riverside (Calif.) under Prof. H. S. Smith, and they serve as a beginning towards a better understanding of the subject. A distinct drawback is the absence of any date indicating when the Bulletin was published.

Pelargoniums

The Pelargonium, which goes too often under the erroneous horticultural pseudonym of Geranium, is a potent and ubiquitous contributor to garden beauty. It is usual to think in terms of one or two species only of this genus, but Sir Arthur W. Hill (*J. Roy. Hort. Soc.*, 64, Pt. 8, August 1939) has recently described a larger number of the 250 species which it actually contains. South Africa is the home of the genus, and more than 200 species grow there. The Dutch were the first to bring over Pelargoniums of horticultural value, and *P. triste* was apparently the first kind to appear in Great Britain, in the year 1632. By 1703, a considerable number of species was in cultivation, and the favourite *P. zonale* was produced by cross-breeding in 1710. Sir Arthur's paper is designed to portray the horticultural possibilities of the genus; he deals with variety in leaf and flower form, outlines the tuberous species, and mentions such kinds as *P. tetragonum* with fleshy stem and cactus-like flower, and *P. crithmifolium* with fleshy leaves.

Crustal Structure of California

Using data obtained by reading seismograms for sixteen near earthquakes and one blast, P. Byerly has determined the structure of the crust of the earth in California and the speeds of the primary and secondary waves in the several layers of the crust (*Bull. Seismol. Soc. Amer.*, 29, No. 3, July 1939, pp. 427–462). The records used were chiefly from Wood-Anderson and Benioff seismographs with a drum-rate of 60 mm. per min. and they were read to the nearest 10^{-1} second of time. The estimate of the dimensions of the crust chiefly rests on the accurate determination of the depth of focus of the Berkeley earthquake of March 8, 1937. These dimensions turn out to be 9 km. of granite overlying a layer 23 km. thick of intermediate material, which itself overlies the mantle. Data obtained for shocks with epicentres to the south of Berkeley were found not to fit this structure, but successfully did so when it was assumed that the granitic layer thickened towards the south. In all the earthquakes considered there was a lag of P_n as it passed under the Sierra Nevada, a fact which had been noticed previously. A reconsideration of the P_n data of the Nevada earthquake of December 20, 1932, together with all the other data, suggests that the root of the mountain mass projects into the mantle beneath the surface layers by an amount between 6 km. and 41 km. The velocities of the P and S waves in the various layers were found to be (*a*) in the surface layer $P = 5\cdot61 \pm 0\cdot05$ km./sec., $S = 3\cdot26 \pm 0\cdot09$ km./sec. and there is a suggestion that these may start from different foci; (*b*) in the intermediate layer $P = 6\cdot72 \pm 0\cdot02$ km./sec. and $S = 7\cdot24 \pm 0\cdot04$ km./sec., though only the former was used for the determination of the structure; (*c*) in the mantle $P_n = 8\cdot02 \pm 0\cdot05$ km./sec.

Age of Meteorites

F. A. Paneth has issued an important paper with this title which describes the methods for determining the age of meteorites and the results obtained (*Occasional Notes Roy. Astro. Soc.*, No. 5; 1939). The most satisfactory formula is derived from the following simple principles: let U and Th be the grams of uranium and thorium present in a sample of a meteorite, and let He be the number of cubic centimetres of helium which have originated from these two radio-elements; then the age in years is

$$\frac{He}{1\cdot14\,U + 0\cdot29\,Th}\,10^7.$$

At one time it was believed that the age-values determined by this method were on the low side, owing to the escape of helium. As Paneth points out, however, temperatures up to 1000° cannot drive out more than about 5 per cent of the helium contained in an iron meteorite, and as only the outermost portion is heated during the flight through the atmosphere, the method is satisfactory for iron meteorites. This remark does not apply to stone meteorites; the stone meteorite Pultusk lost practically all its helium content after 3 hours at a temperature of 800°. Table ii shows the maximum age in millions of years of thirty meteorites. This varies from 2,800 in the cases of Thunda and Mount Ayliff to only 100 with Bethany, Goamus, and Toluca. On the basis of the assumption as to the solubility of thorium in iron, Paneth and his colleagues were of opinion that the real values might be 10–20 per cent lower; but this is an under-estimate. They developed a method for the determination of the thorium content of iron meteorites, preliminary figures for three of which are given, and, though improvements can still be made, they are confident that its quantity in meteoritic iron can be greater than was suspected. The above equation shows that this will diminish the age, and in the case of Bethany, Goamus, the figures are 30 million years instead of 100 million years. The result of the research shows that no meteorites exist with ages greater than that of the earth—a fact which supports the view that the meteorites originated within the solar system. Nevertheless, the low age found seems to give weight to the short time-scale of the universe, that is, that the whole universe is of no greater age than the earth. It seems fairly certain that iron meteorites assumed the solid state at different times, and further research will probably reveal important relations.

THE SIXTH PACIFIC SCIENCE CONGRESS

THE immense area of the Pacific Basin comprises what is perhaps the most fascinating region of the globe. It is bounded on the east, on the north and, as far south as the equator, on the west by volcanic regions indicative of great geological instability. It includes open stretches of sea hundreds of thousands of square miles in extent and contains more than twenty thousand islands, some of them rocky, others volcanic and others again of coral origin. These islands have a distinctive and in many respects a unique fauna and flora. They are populated by most interesting native races, Polynesians, Melanesians and Micronesians, who, coming originally from south-east Asia, settled these widely scattered islands by the most remarkable of all human migrations. There they evolved a civilization which evoked the amazement of those early European navigators who, however unwittingly in many cases, sowed the first seeds of its subsequent rapid decay.

Despite the great pioneer voyages of Spanish, Dutch, British, French and Russian navigators and of New England whalers in the seventeenth and eighteenth centuries and of scientific explorations such as those of the *Challenger* and of the United States exploring expedition under Wilkes in the nineteenth century, the area covered by scientific and commercial surveys up to the beginning of the present century has been aptly described as no more than "a plough furrow in a twenty acre field". To quote from the introductory speech to the Sixth Pacific Congress of Prof. Herbert E. Gregory, former director of the Bernice P. Bishop Museum, Honolulu, and the greatest individual force behind modern scientific study of the Pacific: "The material and records amassed by such long time undertakings as the Wilkes and the *Challenger* expeditions and during the first two decades of the present century by local surveys under the auspices of scientific institutions in England, Scandinavia, Australia, Netherlands Indies, Japan, Canada and the United States is large in bulk and variety. But its study reveals far more questions than answers. It shows that the Pacific is fairly bristling with problems in geography, geology, botany, zoology and anthropology and that the observations recorded here and there in a region that comprises more than a third of the earth's surface are inadequate for comparative studies of the earth's physical features and of the origin, migrations and environment of living forms on the land and in the sea; and that until further knowledge has been gained many of the stories that science has to tell must be incomplete".

Co-ordinated scientific study of the Pacific was discussed at the meeting of the British Association in Australia in 1914 and afterwards in the United States. But it was not until 1920 that, largely owing to the initiative of Prof. Gregory, the first Pacific Science Congress met at Honolulu. This took the form of an informal gathering of some sixty carefully selected delegates from the United States, Canada, Hawaii, the Philippines, the Netherlands Indies, Japan, China, Australia, New Zealand and Samoa. It was realized that a central organization and planned expeditions were impracticable owing to lack of funds, but that a purely volunteer organization could play a great part in the furtherance of research in the Pacific if each unit, while perfecting its own programme, subscribed to a common programme and kept in close touch with associated organizations in other countries bordering the Pacific. While official delegates have been sent by interested Governments to subsequent congresses, these have always consisted essentially of individuals interested in various aspects of research in the Pacific area. This emphasis on the individual rather than on the State and on subjects of general scientific interest, to the exclusion of anything likely to have a political bearing has been the key to the subsequent outstanding success of the Pacific Science Association.

The second Pacific Science Congress was held in Australia in 1923, the third in Japan in 1926, the fourth at Java in 1929 and the fifth in British Columbia in 1933. It was there agreed that the sixth congress should not meet in North America, and the possibility of a congress at Fiji was discussed. This later proved impracticable, while international difficulties steadily increased so that the maximum period of five years between successive congresses was passed without another meeting being arranged. But representations made at Washington to the National Research Council of the United States most fortunately prevented what, as later events have shown, would almost certainly have been a complete break in the continuity of these congresses.

Under the auspices of the National Research Council a sixth Pacific Science Congress was organized and held in and around San Francisco during July 24–August 12, 1939. The meetings were held at Berkeley, Stanford and San Francisco, the University of California and Stanford University acting as joint hosts, and the Golden Gate International Exposition co-operating with them through its Department of the Pacific Area. Prof. Ross G. Harrison was president, and Prof. Roy E. Clausen, secretary-general, of the Congress.

The courageous optimism of those responsible for the organization of the Congress was abundantly justified by the presence of some five hundred delegates, including representatives from Australia, Canada, China, Columbia, France, Great Britain, Hawaii, Hong Kong, Japan, the Netherlands and the Netherlands Indies, New Zealand, the Philippines, Siam, Sweden, the U.S.S.R., and the United States. The discussions covered a wide field, as may be indicated by the nature of the sections and subsections into which the Congress was divided.

Section 1, Geophysics and Geology, dealt with the structure and dynamics of the Pacific basin; section 2, Oceanography and Marine Biology, including Fisheries, with the properties, dynamics and life of the Pacific. Pacific climates formed the subject-matter of section 3, which discussed past climates and also present climates under the two headings of meteorology and climatology. Section 4, Anthropology, dealt with man and culture in the Pacific region and with the objectives and results of the study of these cultures. Section 5 was concerned with the terrestrial faunas of the Pacific islands and bordering countries, and was especially concerned with systematic and economic entomology, including biological control of insect pests, and with medical entomology. General botany and plant diseases of the Pacific region constituted the two subsections of section 6. Section 7 consisted of public health and nutrition, and was divided into subsections dealing with the geography and epidemiology of the communicable diseases of the Pacific region, with health hazards arising from transport, occupation and agricultural practices, with nutritional problems and finally with education in matters of health. Section 8 dealt with the characteristics, utilization and conservation of the soils in the countries of the Pacific.

All who are in any way interested in the manifold scientific problems of the Pacific owe a debt of gratitude to the National Research Council of the United States and to all who pressed, against considerable and not unnatural opposition, for the holding of this Congress. There must be many of the foreign delegates who now feel, with the writer, that this meeting, attended by so many races and nationalities united in the prosecution of disinterested scientific research, will be during the darkness which looms ahead both a memory of a happier past and a foretaste of a more enlightened future. The Congress broke up in the expectation of a seventh Congress to be held in the Philippines in 1943. That the future course of world history makes this possible may well be the wish of every civilized human being.

LOWER PERMIAN INSECTS OF KANSAS

F. M. CARPENTER has recently discussed numerous specimens of fossil insects obtained in 1935 from the Elmo limestone (Kansas), of Lower Permian age (*Proc. Amer. Acad. Arts and Sci.*, 73, 29–70; 1939). More than 8,000 specimens from this formation are now in the collections of the Harvard Museum of Comparative Zoology.

The results of the 1935 collection exceed all others in the number of complete, or nearly complete, specimens that were disclosed. Some of the most interesting fossils obtained are members of the group which Tillyard named the Protohymenoptera, and now regarded as belonging to the Megasecoptera. Thus, in *Permohymen*, the male genitalia are well preserved and are seen to be composed of paired penes with two-segmented claspers which are evidently homologous with the styli of may-flies. Regarding *Asthenohymen dunbari*, 32 specimens were found, and, of these, four present enough of the body structure to allow, for the first time, a complete reconstruction of the insect to be made and the differences between the fore and hind wings to be ascertained. In one example the ovipositor is well preserved.

The Protodonata that were collected on the 1935 expedition proved to be unusually interesting. In the first place the discovery of *Meganeuropsis permiana* gen. et. sp. nov. from the Permian of Elmo constitutes the first example of a Meganeurine occurring in the New World and also in rocks of Permian date. Dr. Carpenter discusses the affinities of the family Meganeuridæ, and does not accept Martynov's contention that they should be placed in the order Odonata as true dragonflies: he concludes that there is no justification for their separation from the Protodonata until it is proved that the Meganeuridæ had a phylogenetic origin different from that of the other families of that order.

The author then passes on to deal with the Homoptera. Altogether twenty-six specimens belonging to this group were collected. While none of the species is new, the material adds to knowledge of the body structure and the hind wings of the Homoptera. In *Permocicytina kansasensis* Till. the single specimen obtained during 1935 shows a long process extending straight back from the end of the abdomen: being 9 mm. long, it exceeds the length of the combined thorax and abdomen. Dr. Carpenter concludes that it is not an ovipositor but rather of the nature of a respiratory tube such as is found in water bugs of the recent family Nepidæ. This contention presupposes that the insect was aquatic, but there appears to be no indication of any modification of the rest of the body from an aquatic environment, a feature shown in the recent family Nepidæ.

The remainder of the paper deals with the Psocoptera, Protelytroptera and Protoperlaria.

A. D. I.

INVENTIONS AND PATENTS IN GREAT BRITAIN*

THE fifty-sixth report of the Comptroller-General of Patents, Designs and Trade Marks for 1938, records a further increase in the number of patents, applications having increased from 36,266 in 1937 to 37,973 in 1938, with increases in the number of provisional and complete specifications from 21,745 and 22,215, respectively, to 26,696 and 23,098. In regard to the trend of inventions, the synthetic production of artificial wool and rubber, the latter by the polymerization of diolefines and halogenated diolefines, continues to be prominent. New developments in the very active field of synthetic resins are the use of polyamide resins for making artificial yarn and the use of resins in water purification by ionic exchange. Antioxidants or stabilizers for rubber, oils, fats, soaps, aldehydes and light-sensitive substances are much in evidence. Applications relating to azo and vat dyes decreased in number, but the development of long-chain polymethine dyes for use as photographic sensitizers is actively sustained.

---

* Patents, Designs and Trade Marks. Fifty-sixth Report of the Comptroller-General of Patents, Designs and Trade Marks, with Appendices, for the Year 1938. Pp. 26. (London: H.M. Stationery Office, 1939.) 6*d*. net.

The manufacture of glass fibres of extreme fineness and the use of short-path high-vacuum distillation for the concentration of vitamins have received attention, as well as directional wireless systems in relation to the navigation and blind landing of aircraft. Notable developments with electron microscopes relates to the magnetic lens systems, the arrangements for inserting the object under examination and the use of a fine scanning beam in place of a fixed electron beam. Methods of giving air-raid signals over electric power networks are being explored, and another interesting development is concerned with the speedy testing of watches, for accurate time-keeping, by electric means. A notable feature has been the production of vehicle bodies and aircraft fuselages and girders from synthetic resins. Mechanical remote-control systems are being devised to free the floors of motor-vehicles from obstruction by control levers, while another field of activity has been in gyroscopic instruments for indicating the course and altitude of flight of aircraft and in the automatic supervision, by means of magnetic compasses, of course-indicating gyroscopes so as to eliminate wandering.

Applications for designs and registered designs both decreased in number compared with 1937, but registered trade marks increased.

GEOGRAPHICAL DISTRIBUTION OF THE COWRIES

In the study of the geographical distribution of the littoral marine fauna, the Mollusca claim special attention, since the activities of collectors have provided far more abundant data regarding them than are available for any other group of marine animals. More especially is this the case with such groups as the large and handsome tropical cowries and cones which have been favourites of the dilettanti for two centuries at least. It is true that a great deal of the older work on them is without any scientific value; endless lists of 'varietal' names have been given to individual abnormalities, environmental modifications, and stages of growth, while localities have been vaguely or incorrectly recorded. Nevertheless, it has long been obvious that a great amount of valuable material was awaiting scrutiny by modern methods.

This has now been done for the cowries by Dr. F. A. Schilder and Dr. M. Schilder in a "Prodrome of a Monograph on living Cypraeidae" (*Proc. Malacol. Soc.*, **23**, Pts. 3 and 4; 1938–39), in which a revision of the whole family is given, together with a detailed analysis of the distribution of the species and subspecies composing it. The material studied by the authors comprised more than 60,000 shells, in some eighty public and private collections in Europe. They recognize 165 species, nearly all of which are further subdivided, each into two or more geographical races or sub-races. The races and sub-races are treated together for nomenclatorial purposes as sub-species, and they "can be recognized at least by the sum of several variable characters of the adult shells and by the fact that each race has usually its own centre of distribution where it is relatively more frequent than at the periphery". The species and races are further grouped into units of higher order designated 'super-species', which are equivalent to the *Rassenkreise* of Rensch, and are defined as "the sum of the allied species and sub-species inhabiting a mostly continuous region and geographically separate from each other".

The authors' conception of a super-species is not very easy to grasp, and it must be said that their exposition is not everywhere a model of clarity. For example, the statement that "in some genera several evidently allied species inhabit the same region; they must each be treated as different superspecies" would seem difficult to reconcile with the definition just quoted. It can be so reconciled, but only to leave one in doubt whether the idea of super-species is worth very much after all.

Nevertheless, the monograph deserves careful study as perhaps the first attempt to apply on a large scale to marine animals those methods of geographical delimitation of races which have hitherto been applied almost exclusively to terrestrial and freshwater organisms.

W. T. C.

THE BREEDING OF OYSTERS*

Experiments on the breeding of oysters in large concrete tanks have been in progress at Conway, North Wales, since 1919. The ultimate aim of the work has been to provide a simple and efficient means of procuring the settlement of large crops of oysters in tanks, in the belief that such a method would prove of value to the oyster growers in replenishing their stocks. Mr. Cole has already explained his methods in two previous papers: 'Experiments in the Breeding of Oysters (*Ostrea edulis*) in Tanks, with Special Reference to the Food of the Larva and the Spat" (Fishery Investigations, Series II, 15, No. 4, 1936) and "A System of Oyster Culture" (*J. du Conseil*, 13, No. 2, 1938). It is now believed that this aim has been realized and that spatfalls of commercial magnitude may be obtained regularly in the Conway tanks.

This work is of great interest and importance and based upon years of labour, early experiments having been made at Conway by Dr. R. W. Dodgson and Mr. H. P. Sherwood.

The main plan is to enrich one large tank gradually by the addition of finely ground crab meat, whilst the other is left untreated. Smaller tanks are also used for breeding. The purpose of the organic enrichment is to bring about the multiplication of minute flagellates which we now know to be the food of the free-swimming larval oyster. Oysters placed in the tanks liberate their shelled larvæ which in both treated and untreated tanks settle as spat, but in the enriched tank the number settling is found to be much greater. Very heavy spatfalls were obtained in the tanks on limed tiles in both 1937 and 1938, and the commercial possibilities of this method of obtaining the settlement are clearly demonstrated. In both these years there was a nannoplankton consisting almost entirely of very small flagellates, and the ability of the oyster larvæ to feed on such flagellates has been confirmed by laboratory feeding experiments, which have also shown that they can not utilize non-motile green and blue-green algæ during the free-swimming period. The higher concentration of flagellates in the treated tanks is favourable to rapid growth and settlement of the larvæ.

---

* Fishery Investigations. Series II, 16, No. 4. 'Further Experiments in the Breeding of Oysters (*Ostrea edulis*) in Tanks", by H. A. Cole, Ministry of Agriculture and Fisheries. (London: H.M. Stationery Office, 1939.)

The length of the larval free-swimming period under tank conditions varies between seven and fourteen days, ten days being the average. Between a temperature of 16° and 22° C. the length of the free-swimming period does not vary more than a day or two and, after liberation, food supply rather than temperature appears to be the critical factor. Temperature, however, affects the spawning, but the relation under tank conditions is complex. Spawning does not usually occur below 17° C. A sudden rise of 2°–3° C. around a temperature of 16°–17° C. is likely to produce spawning among ripe females. Sustained high temperatures (19°–20°) may have the same result.

It is interesting that some of the experimental larvæ reached an enormous size (0·35 mm.) before attachment, the usual size being 0·18–0·20 mm. on liberation and 0·28–0·31 mm. on settling.

The bulk of the limed tiles on which the spat has settled is removed to shallow tanks filled with water from the estuary. In this way they get the much larger amount of food necessary in the fixed stage. Later the tiles are planted out in the Menai Straits, where the oysters grow rapidly. Most of the spat planted in August 1938 was only three weeks old, but it is believed that such early planting does not lead to maximum survival. It seems that it is best to delay the planting out until the individual spat are about 5 mm. across. Unless the settling season is unusually late it is found that spat planted out in the autumn should be large enough to detach from the tiles by the following May or June. A size of 2 cm. should be reached in ten months. After detachment the spat is placed fairly thickly in shallow wire-covered trays, raised on the bottom. Growth is rapid. These oysters should be ready for planting on firm bottom without protection when twenty months old, the average size of a good sample of brood from the Conway tanks at this age being about 5 cm. Samples of such broods have been sold to the oyster growers and have done well after transplanting.

It is encouraging to realize that the tank breeding process may be put forward as a possible means of replenishing the stocks of home-grown oysters on British beds, and that Mr. Cole is justified in his statement that "the results of these three years (1936, 1937 and 1938) taken together, fully warrant the conclusions that a commercial crop of oyster spat can be obtained annually, with reasonable certainty".

SCIENCE NEWS A CENTURY AGO

The Steamship *President*

The *Annual Register* for 1839 records that on October 7, "Several thousand persons went to Limehouse to view the immense steamship the *President*, built by Messrs. Curling and Young for the British and American Steam Navigation Co., and intended to run between New York and London. The *President* is of greater power and tonnage than the *British Queen* (the former being of 600 horse power and 2,336 tons, the latter 500 horse power and 2,016 tons), and was built in the same dock, and not upon a slip; so that she had to be floated out of dock, and not launched. At high tide, however, which happened to be a low tide, there was not enough water to float her, and she remained fast aground aft. Mrs. Laird, wife of the African explorer and projector of Atlantic navigation by great steamships, performed the ceremony of christening, amidst the cheers of the multitudes on the banks and on the river. . . . On Monday the 9th, the water being sufficient, the *President* was floated into the river and towed to Blackwall."

The *President* was the largest of the pioneer Atlantic steamships, but her career was a very short one. She left New York on March 11, 1841, on her third homeward voyage, and foundered next day in a gale, all aboard being lost.

Royal Cornwall Polytechnic Society

The seventh annual meeting of this Society was held on October 8, 1839, in the Polytechnic Hall, Falmouth, Sir C. Lemon, M.P., being in the chair. Several premiums were awarded for mechanical and scientific inventions and improvements. Among the notices in the report was a reference to Prof. Moseley's suggestion for calculating the "Efficiency of Steam Engines", a matter of great interest to all Cornish engineers. His proposal was to use a small cylinder, of about six inches diameter, connected with the large cylinder of the engine, the piston in the small cylinder being acted upon by a spring. Prof. Henry Moseley (1801–72), F.R.S., whose writings on mechanics, etc., were well known, was professor of natural philosophy in King's College, London, and afterwards one of the first of Her Majesty's inspectors of schools, and canon of Bristol. He was the father of H. W. Moseley (1844–91), Linacre professor at Oxford and grandfather of the physicist H. G. J. Moseley (1887–1915), who was killed in Gallipoli during the Great War.

Electro-magnetism as a Motive Power

Dr. Jacobi, said the *Athenæum* of October 12, 1839, in a letter to Faraday thus alludes to this subject:

"In the application of electro-magnetism to the movement of machines, the most important obstacle always has been the embarrassment and difficult manipulation of the battery. This obstacle exists no longer. During the past autumn, and at a season already too advanced, I made, as you may perhaps have learned by the gazetter, the first experiments in navigation on the Neva, with a ten-oared shallop furnished with paddle-wheels, which were put into motion by an electromagnetic machine. Although we journeyed during the entire day, and usually with 10 or 12 persons on board, I was not well satisfied with this first trial, for there were so many faults of construction and want of insulation in the machines and battery, which could not be repaired on the spot, that I was terribly annoyed. All these repairs and important changes being accomplished, the experiments will shortly be commenced. The experience of the past year, combined with the improvements of the battery, give as the result, that to obtain the force of one horse (steam-engine estimation) it will require a battery of 20 square feet of platina distributed in a convenient manner, but *I hope* that from 8 to 10 square feet will produce the effect. If heaven preserves my health, which is a little affected by continual labours, I hope that within a year of this time I shall have equipped an electro-magnetic vessel of from 40 to 50 horse-power."

The author of these experiments, the first made on electric propulsion, was Moritz Herman von Jacobi (1801–1875), who for many years was a professor at St. Petersburg.

Medical School at Athens

The issue of the *London Medical Gazette* of October 12, 1839, contains the following information: "An attempt is making at Athens, the present capital of the modern Greek Empire, to organize a medical school, by several well-educated and respectable Bavarian physicians and surgeons, who are attached to the Court, and whom King Otho has induced to settle in his country.... They had from nine to twelve pupils, natives of the country, who were lectured to by a German in the modern Greek language; the professors, from a residence of several years in the country, being able to impart instruction to their pupils in their native tongue. Although it is the merest beginning of a medical school, it is nevertheless praiseworthy and honourable in its present founders, and may be the germ of an institution which shall move onward hand in hand with the regeneration of poor fallen Greece. . . . Athens possesses at this moment a most excellent military hospital, arranged upon the modern European plan, capable of containing very comfortably several hundred patients. Also a highly respectable and well-arranged cabinet of Natural History."

Subterranean Forest

The *Gentleman's Magazine* for October 1839 contains the following information: "The capacious bonding pond, which is now being excavated at South Stockton, has led to the discovery of an extensive subterranean forest. The timber is chiefly oak. A yew tree, of considerable size, has been found, the wood of which is sound and good and fit for the turner's lathe. Many of the oaks are of large dimensions, and it is expected that some of them will be suitable for the purpose of building. Whilst examining this forest, Dr. Young of Whitby, with some friends discovered one of the oaks to have been cut in two, which had evidently been done previous to its being covered by the earth. He supposes the forest must have been cut down by the Roman soldiers, as they were in the habit of laying timber on the low swampy grounds for the purpose of making roads. Be this as it may, it is certain the hand of man has been exercised on the timber, and it may form a fertile subject for the lover of ancient history and the geologist to speculate on".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned.

Assistant I (reference B.401) and Assistant II (reference B.402) at Air Ministry Headquarters—The Under Secretary of State, Air Ministry, Department ZA (B/127), Harrogate, Yorks (October 13).

Commissioned Ordnance Mechanical Engineers in the Indian Army Ordnance Corps—The Secretary, Military Department, India Office, S.W.1 (quoting O.M.E. Recruitment) (October 17).

Assistant Engineer for the Drainage and Irrigation Department, Malaya—The Crown Agents for the Colonies, 4 Millbank, S.W.1 quoting M/5765).

Meteorological Assistants (Male) in the Meteorological Office—The Under-Secretary of State, S.2.B.(Met.), Department Q.J., Air Ministry, Adastral House, Kingsway, W.C.2.

A DIRECTORATE OF SCIENTIFIC INFORMATION

THERE are those who affect to believe that scientific people are somehow responsible for the war: whereas, in fact, because of the international character of their interests and friendships, they are singularly innocent. Each generation tends to imagine that its own experience, like its fashions of thought, expression or personal adornment, is unique. This war, therefore, must have some special cause—why not blame it on science? The fact is that history books are already full (too full) of conquerors out for glory and loot, guilty of persecution and treachery, moving masses of ordinary decent men to follow them in hysterias worked up by appealing to fear, hatred and greed.

It is true, nevertheless, that the special character of this war, as to some extent of the last, depends very largely on science: not in its ferocity or its attacks on civilians, as the story of the Thirty Years War—and of many others—will show: but in its speed, its weapons of offence and defence, its transport, its communications. It is a scientific war, and one chief factor in winning it will be to employ the methods of science quickly and to the best advantage; not only in offence and defence, in interception and attack, but also in maintaining the ordered life and well-being of the community on the home front.

In the Service ministries and in civil defence the directors of scientific research have large resources and organizations at their disposal. The Department of Scientific and Industrial Research, the Medical Research Council and the Agricultural Research Council advise these and other ministries, and many of the latter have scientific advisers and establishments of their own. The Ministry of Information alone appears to have no special organization from which scientific advice, scientific criticism and scientific fact can be obtained. It is now in course of reconstruction, and we may hope that the omission may be repaired. For the war is a scientific war, and the science of it is not all so secret or so unintelligible that it cannot usefully be made public. If, as Mr. Wilfred Trotter maintained in a striking letter in *The Times* of September 25, our chief advantage over the Nazis lies in the free use of our minds, there should be a special place for science, and its services to the national cause, within the structure of the Ministry of Information.

This view may seem strange, even amusing, to senior administrators of the old type, trained perhaps thirty years ago in a school of ancient philosophy. It will not seem so strange to their younger colleagues, and not at all strange to the large number of skilled working people who are perhaps the most important class in our community. To many of the latter, science is a thing of high repute, and information and advice given in technical and scientific form (provided that is not too dull) carries special conviction. The nation has particular need of their help, their technical skill and resource: it will receive them the more freely if, within the limits of necessary secrecy, they can be told how and why.

During the war, the lives of many of us will be greatly, if temporarily, changed. Scientific knowledge will be needed to ensure that home supplies of food are increased in the right and most economical way; that the food is efficiently used and a high standard of nutrition maintained; that major epidemics are avoided; that medical treatment is forestalled, or economized, by preventive measures and an insistence on public health. In all such matters great improvement is possible: we lag, for example, far behind Holland, Norway, Australia and New Zealand in avoiding infantile mortality. Persistent education, therefore, is required giving scientific reasons in popular form, if standards of life are to be maintained, or —as they ought to be—improved. We say improved. To reduce, for example, the infantile mortality (under one year) to that of Holland would, in a three years war, save more than fifty thousand children whom we shall badly need in the future; apart from the saving of health and lives in the later years of the rest. Persistent propaganda by the Ministry of Information could help to move public authorities, and the people themselves, to take what steps are possible in all such respects: and that propaganda, to be convincing in quality and effective in results, should be based on scientific knowledge.

In other material respects the life of the community must be altered. 'Black-outs' and air-raid precautions, fuel rationing, limitation of transport and communications, the transfer of manufacturing capacity to munitions, the necessity of using home supplies, where possible, of raw materials; all these, and many others, involve scientific knowledge, investigation and adjustment. Often it will be useful and encouraging to our own people, valuable to our prestige abroad, and no help to the enemy, and will assist in removing misunderstanding and lack of confidence, if scientific reasons can be given frankly (when they exist) for action which the Government has to take. In a community of free people, good will and understanding are incalculable assets, and can be obtained by confident, frank and accurate statement of the facts; which can often be expressed in scientific or statistical terms. A Director of Scientific Information, with a small scientific staff, some of whom should be experienced in journalism, having good outside contacts among scientific people, would serve a similar purpose in this respect to the directors of scientific research in the Service ministries.

In the fighting services themselves the methods of defence and offence are largely scientific. Some of these methods are highly secret: others are well known to the enemy. There could be no conceivable harm, and there might be great good, in informing the public freely of the latter. To take a trivial example, ingenious persons could be saved the trouble of working out devices which are either known already or impracticable, and inventions committees could be saved the trouble of examining and replying to them. Moreover, and this is not trivial, information not obviously secret which could be used by an intelligent scientific enemy, might be saved from publication by the scrutiny of an alert scientific censorship. In the absence of such scrutiny, the present danger is that everything scientific may be censored, even laws of Nature.

There is intense anxiety on the part of the scientific community to be of service, and progress may seem slow in utilizing some of the best brains available. This anxiety leads to recurring suggestions that a Ministry of Science should be set up, or that research should be 'co-ordinated' on a grand scale by a National Research Council of some kind. It is really better to work by and through existing agencies, with additions where necessary, and long experience in the last war and since has shown that bright ideas advanced by ingenious minds not in touch with actual needs are of little value compared with direct attack, by orthodox scientific methods, by those who are in touch.

The important thing is to provide facilities for able young scientific men (the older ones are largely in touch already) to make contact with various practical problems of national importance. The problems cannot all be predicted beforehand; some will arise as the war goes on. Nor, for reasons of necessary secrecy, can they always be publicly announced. Within such limits, however, as are necessary, the more clearly the scientific aspects of practical problems can be stated, the more chance is there of the right scientific people emerging to attack them. These problems are not only those of the fighting services; they are also connected with the whole life and activity of the nation. From the wide contacts it will have, the Ministry of Information, through its scientific staff, could act to a significant extent as a clearing-house of scientific ideas, problems and persons.

We do not wish to exaggerate the part which science has to play in the task which lies before us; and we are well aware how much already is being done in the use of scientific methods and research for national defence. Measured in terms of its necessary establishment, a Directorate of Scientific Information would be an insignificant addition to the Ministry; its usefulness, however, under wise guidance, might be great beyond comparison.

THE SOIL AS THE BASIS OF PROSPERITY

(1) The Rape of the Earth
A World Survey of Soil Erosion. By G. V. Jacks and R. O. Whyte. Pp. 314+47 plates. (London: Faber and Faber, Ltd., 1939.) 21*s.* net.

(2) Land Utilization in Australia
Issued by the Australian Institute of International Affairs under the auspices of the Institute of Pacific Relations. By Prof. S. M. Wadham and Prof. G. L. Wood. Pp. xix+360. (Melbourne: Melbourne University Press; London: Oxford University Press, 1939.) 21*s.* net.

(1) MESSRS. Jacks and Whyte have followed up the important bulletin on soil erosion which they prepared for the Imperial Bureaux of Agriculture at Rothamsted and Aberystwyth, by a more general survey of the subject in which they proceed from a description of erosion the world over to a discussion of its consequences—economic, social and political. In the earlier chapters they explain that erosion has been of long standing in the Eastern Mediterranean countries, in India and China, but has come into prominence of recent years since the spectacular destruction in North America, which directed attention to similar processes at work in Africa and Australia, even in New Zealand. Everywhere man has been the cause; reckless deforestation, which bared the hill slopes, turned the river valleys into swamps and choked the harbours; over-hasty agriculture, which left the soil without any binding power; over-grazing, which destroyed the natural protective cover. Yet neither forest exploitation nor agriculture need be destructive; the Old World offers many examples of how production may be maintained indefinitely without loss of fertility. But these lessons have been ignored wherever men have been allowed 'to do what they like with their own'—their own in this case being the land; so that the vast expansion of population in the nineteenth century induced such a hurried exploitation of the land that the world's productive capacity has been permanently impaired.

So far as Great Britain is concerned, erosion is not a problem; with our evenly distributed rainfall and humid atmosphere we can grow grass, and on the basis of an alternation of grass and arable crops we can both protect the soil and maintain fertility. Indeed, even where the conditions are less favourable to grass, as on the great plains of Russia or North America, the evolution of a conservative system of farming will depend upon the introduction of longer or shorter periods of grass to enable the soil to regain its texture with the accumulation of humus and nitrogen. It is in Africa that the problem of erosion presses most upon us, for in the East African Colonies, in particular, the waste of the soil and the growth of the desert has already progressed so far that the land is unable to carry the native population, still less to give them that surplus production which is required for their physical and cultural improvement. In Africa more land for the natives and land for the absorption of surplus population of European origin is almost out of the question; the continuance of the native population is threatened and we are trustees for their well-being. Such questions are discussed by Mr. Jacks in the closing chapters of the book; they are questions that no statesman can ignore.

The book is excellently produced; the illustrations alone are capable of telling most of the story.

(2) "Land Utilization in Australia" is a book commissioned by the Australian Institute of International Affairs, as the national group of the Institute of Pacific Relations. Though it touches on soil erosion, it is mainly a thoroughly documented account of the development of agriculture in Australia and of the possibilities of expansion and closer settlement. Profs. Wadham and Wood are insistent upon the small proportion the cultivable land bears to the superficial area of that continent; even the tropical regions of Queensland and the Northern Territories offer little promise of economic utilization.

The summary of land use shows 40 per cent of 'waste', that is, desert and semi-desert, 3 per cent of crops and orchard land, and 2 per cent of forest, 55 per cent being classed as pasture and rough grazing. But the greater part of this latter area would better be described as ranching land with a low stock-carrying capacity, and dangerous to bring under cultivation. It is interesting to note that the population employed in agriculture has actually declined since 1914, though the gross production has increased. This represents technical improvement and the greater use of labour-saving machinery (probably in no country is the output per man equal to that in Australia), but the shrinkage in the agricultural population is a token of how little is the marginal land available for higher production. Since the War of 1914–18, there has been no lack of schemes for closer settlement and assisted emigration, but progress has been halting and the cost great.

So far as the descriptive part of the book goes, a discussion at this distance would be irrelevant; Profs. Wadham and Wood have done their work well and have produced an indispensable work of reference. But in their later chapters they enter on more general ground by a consideration of how the future agricultural development of Australia is likely to be influenced by changes in the world's markets.

The growth of Australia in the nineteenth century was the outcome of the great increases of population in Western Europe; economically, it was based upon international trade, upon the exchange of food and other primary products for capital and manufactured goods. But the equilibrium has only been temporary; we have now a stationary population in the Old World, accompanied by a marked increase in the power of industrial production. That ought to have led to a freer exchange of commodities and a rising standard of living all round; but country after country has intervened to protect its politically dominant agriculture against the rising tide of cheap food from the new countries The years 1914–18 brought their own dislocations of the mechanism and particularly generated an excessive nationalism which led every country to aim at being self-sufficient.

In this way we have arrived at a world economy based upon scarcity and high internal prices just when the powers of production, industrial and agricultural, are rapidly expanding. Australia stands to be hard hit; so far as manufactured goods go she has joined the ring and maintains high internal prices. At the same time, her cheap agricultural production is rendered futile by the diminished purchasing power of her customers in markets like our own, where prices have been raised for the benefit of the home producer but in which artificial enhancement the Australian is not allowed to share.

It is a bad look-out for agricultural progress, not only in Australia but also everywhere else, until the world begins to act on the fact that plenty is at our disposal whenever we are so minded.

HOW GENETIC SYSTEMS COME ABOUT

The Evolution of Genetic Systems
By C. D. Darlington. Pp. xi+149. (Cambridge: At the University Press, 1939.) 10s. 6d. net.

A MORE comprehensive and intricate mass of material has been successfully analysed and integrated in this masterly exposition of Darlington's than in any other biological treatise of such small size known to the reviewer. The book is not to be recommended to those who are reluctant to read closely and to do a good deal of hard thinking; and it will displease both those who abhor a contemplation of the forest because of its trees, and those who find it too irksome to study the trees because of the forest. But for those willing to make the effort to understand both in their relations to one another it will prove brilliant, illuminating and highly stimulating, no matter whether or not they agree with all the details in Darlington's remarkably coherent and unifying system of interpretations.

As the account develops, one is made increasingly aware of the fundamental importance not merely of the specific attraction between like genes (and gene parts ?) but also of that peculiarity in this attractive force which causes it to be largely satisfied by a two-by-two association, that is, pairing. In the first place, this allows the autosynthetic doubling or 'division' of chromosomes into sister chromatids, and the holding together of these chromatids in mitosis until anaphase; and in meiosis the cause of pairing of the homologues is traced to their entering the prophase with their attractions unsatisfied because of their delayed doubling; this is in fact the crucial point in Darlington's 'precocity' theory. In conjunction with this, a theory is developed which explains crossing-over as a result of the strain arising in the entwined partners when, each having finally doubled, the attractions between the sister chromatids interfere with the conformation that expressed the attraction between the homologues. It may, by the way, be noted that if this were not the actual mechanism, we might have expected to find some organisms in which crossing-over occurred without doubling and in which, accordingly, there was but one meiotic division. Then, crossing-over having occurred, it is shown how this is necessary for holding the group of four chromatids together, and hence for all orderly segregation, despite the fact that the attractions are primarily in twos. These two-by-two attractions, applied to the four chromatids, cross-over and non-cross-over, and taken in conjunction with the non-specific repulsions existing between all chromosome parts, are shown to explain the various peculiar arrangements seen in meiosis in normal individuals of different kinds, and in all sorts of species hybrids, structural hybrids, haploids, aneuploids, and auto- and allopolyploids.

This analysis of the mechanistic interrelations is, however, but a part of the story. The steps are also explained whereby the wide differences in chromosome structure and behaviour, and in the consequent visible results of breeding, between present-day species—in a word, the differences between *genetic systems*—had their origin in gene mutations, breakage and union of broken ends of chromosomes, and chromosome number changes, and it is shown how these steps happened to persist and become accumulated in given sequences, under the guidance of natural selection. The natural selection may be longer or shorter sighted, according to whether the predominant factor in it is the ultimate advancement of the group, which demands the advantages given by a wide (but not too indiscriminate) opportunity for recombination, or the immediate vigour and rapid reproduction of the individuals, which gains by fixed hybridity, polyploidy and asexual reproduction; usually some compromise, more or less vacillating, between the two is reached. The resultant evolution is traced from the stage of the naked gene, through the formation of chromosomes, then sexual reproduction, sex differentiation, and finally through various elaborations, such as polyploidy, permanent structural hybridity, or apogamy, that often represent a form of degeneration of sexuality. In the light of these considerations, various observed details of the cytology and genetics of reproduction, such as the average chromosome length and number in a species, the frequency and the degree of localization of chiasmata, the degree of terminalization, etc., become much more understandable.

Thus all the tangled skein of phenomena which it has been the painstaking task of the past two generations of descriptive cytologists and geneticists to disclose are protrayed as natural developments of a few fundamental principles. These are: the existence of mutable, self-reproducing genes, arranged in the form of chromonemata, the properties of spiralization, of breakage and reunion, and of non-specific repulsion, of these threads, the specific attraction between like genes and gene parts, and the peculiarity that this attraction is largely satisfied by their paired (two-by-two) association. Good evidence for nearly all of these principles (for all except the fusion of broken ends) has, to be sure, been known for more than a quarter of a century—just as evidence on which Darwin's theory of evolution by natural selection might legitimately have been founded had been known for hundreds or even thousands of years before his time—but the great majority of observers failed to recognize these principles, and failed still more to realize their manifold and far-reaching significance when considered in connexion with one another, and in the variations of their expression that would necessarily have developed in the course of evolution, under the guidance of natural selection.

In so comprehensive and condensed a work it is to be expected that there will be not a few passages the clarity of which would benefit greatly by expansion and by more detailed figures, a number of steps of deduction which at first sight at least appear questionable, and some relatively unimportant inaccuracies. Moreover, many of the arguments would probably have gained quicker acceptance if more tentatively presented to a scientific public working in a field in which sound inference has been, comparatively speaking, so rare. Yet the intrinsic importance of the conclusions is so great, and the case made out for them so strong, that it will be impossible not to take them very seriously. The provocative form of expression used, the terseness, elegance and verve of style, the penetrating flashes of imagery and the succession of scientific *bons mots*, may have a salutary effect in shaking what has at times seemed a torpid subject out of its complacency and into a more vigorous life.

The newer life of cytogenetics must consist not merely of a struggle to confirm or refute the above system of concepts. While this work will now continue more vigorously than before, it is really in an advanced stage already—thanks largely to the wealth of Darlington's own observations and analyses and those of his collaborators. But, standing on the basis of these principles, or of any further modifications and clarifications of them, the subject is by no means closed; as readers of the book will feel, it is moved to a higher plane, in which a set of newer problems now emerges for study. An example of these is the question: If the same specific attracting force leads to gene doubling (by attraction of like gene parts from the medium) and to pairing of sister or homologous chromatids, what decides that the result shall at one time be the former, at another the latter? Again, what factors condition variations in the strength of this force, and in the amount of residual attraction after it is partly satisfied by pairing? Why are there not some organisms that, lapsing from the full advantages of sexuality, forego crossing-over and the second meiotic division, while retaining segregation? How is it that the old chromonema coils progressively loosen while at the same time a new, tighter coiling develops, wave on wave? What are the mechanics of a 'twisting' strain that is entirely compatible with fixity of the ends of the threads concerned (as shown in ring chromosomes and those in inversion loops)? What are the interrelations of the forces between the centromeres and those on the mitotic spindle, leading to the co-orientation of paired centromeres?

The day cannot long be postponed when the help of the physicist and chemist will be required in such problems, but without the prior work of the analytical biologist in laying the problems bare, the former would be operating in a fog which they by their own unaided efforts would never have been able to penetrate; and whatever their answers may be, the biological factors themselves, in their interactions in the course of evolution, furnish the keys for the understanding of the complications of the genetic systems existing at the present day, and for the prediction of what will happen to them in the future. Darlington's work goes a long way in making clear the significance of these keys. H. J. Muller.

USE OF MATRICES IN AERONAUTICAL COMPUTATION

Elementary Matrices
and some Applications to Dynamics and Differential Equations. By Dr. R. A. Frazer, Dr. W. J. Duncan and A. R. Collar. Pp. xvi+416. (Cambridge: At the University Press, 1938.) 30*s*. net.

ONE of the serious limitations to scientific development is the amount of labour involved in computation, and the authors of this book on matrices have put on record processes which they have found of value in dealing with certain difficult problems arising in aeronautics. The general class of research in which progress has been made by the authors is that in which elastic deformation of the structure of an aircraft under aerodynamic reactions leads to forced vibrations known technically as 'flutter'. The prevention of flutter in aircraft is obviously important, and the later chapters of the present volume deal with the most recent aspects of flutter research.

Although matrices provide a valuable method of investigation, it should not be concluded that their use is simple in all cases; on the contrary, much labour may be involved, and some energy is being devoted to the provision of a machine for the performance of the multiplication of matrices and the storing of the products for subsequent use.

Using the standard dynamical equations, Routh and others showed that the equations for the disturbed motion of a steady state could be reduced to forms having well-known solutions. In the case of aeroplane stability as well as of flutter, this line of attack has led to valuable results; an essential feature, however, is an inability to predict oscillations of constant amplitude. The use of matrices has enabled the authors to extend analyses to this case; one of the results is to show that frictional resistance may reduce the flying speed at which flutter occurs.

Computation by means of matrices is probably very unfamiliar, and for that reason the book may seem to make heavy reading; each of the steps is easy to follow, but the number of new processes to be absorbed by anyone coming to the subject for the first time is large. The matrix itself is a simple quantity consisting of a number of rows and columns of figures such as would be found in the better-known determinant—with this difference, the rows and columns need not be equal in number. The matrix consists simply of these numbers and, unlike the determinant, has no simple meaning corresponding with the numerical value of the determinant. Theorems are built up for the addition and multiplication, etc., of matrices, and the definition in the case of multiplication leads to a product which depends on precedence; there are, in fact, two processes, pre-multiplication and post-multiplication of matrices.

The earlier part of the book, almost half, is devoted to the detailed consideration of processes with symbolical and numerical illustrations. In Chapter iv, consideration of the use of matrices in connexion with the solution of mathematical equations is begun. One of the early examples is the evaluation of a determinant and another the closely related problem of the solution of simultaneous linear algebraic equations. It is when attempting to follow such solutions in detail that it is brought fully home that a new technical language has been developed, and that this must perforce be learned before independent progress in computation is possible. On the other hand, the methods, once learnt, seem to be powerful.

The book finally leads up to the use of matrices in solving statical and dynamical problems, and Chapter x gives a clear indication of the nature of the problems for which matrices have been found valuable; the examples include oscillations of a triple pendulum, symmetrical vibrations of an annular membrane, the static twist of an aeroplane wing under aerodynamic load. The last three chapters of the book deal with the effects of friction on motion, and the illustrations are taken from aeronautical engineering; it was the difficulty of dealing with this problem which seems to have led the authors to consider the use of matrices.

There can be little doubt that the book has put into the hands of computers a collection of processes which will help in the extension of knowledge, and although the number of interested workers may at present be small, it is to be expected that it will increase.

OCEANOGRAPHY OF THE EAST INDIES

The Snellius Expedition
in the Eastern Part of the Netherlands East-Indies, 1929–1930, under Leadership of P. M. van Riel. Vol. 1: Voyage. Chapters i–iv. Pp. viii+178+31 plates. 20 guilders. Vol. 2: Oceanographic Results. Part 4: Surface Observations, Temperature, Salinity, Density. By S. W. Visser. Pp. viii+62. 5 guilders. (Leiden: E. J. Brill, Ltd., 1938.)

To the oceanographer the eastern part of the Malay Archipelago is one of the most interesting regions of the world. The *Challenger*, *Gazelle*, *Siboga* and *Planet* showed that it consists of a number of enclosed seas, often of great depth, which are separated from one another or from the surrounding oceans by much shallower sills. They are filled from sill level downwards with the densest water which can gain access to them, the water at the depth of the sill. Thus the Sulu Sea has a temperature of more than 10° C. from 400 m. to the bottom in 4,400 m. The oceanography of such a region must depend to a very large extent on the contours of the bottom, but no detailed survey was possible until the invention of the echo sounding gear.

The *Willebrod Snellius* was built by the Netherlands Navy as a surveying ship for use in the East Indies and was fitted with all the latest apparatus for hydrographic and scientific work; the expedition was her first commission. The leader of the expedition was P. M. van Riel, a retired naval officer and the director of the branch of the Royal Netherlands Meteorological Institute at Amsterdam. In the first chapter of vol. 1 he writes on the general plan of the expedition and the voyage out. In the third chapter he gives a short account of the scientific cruises in the survey area with notes on some of the most interesting observations. A remarkable feat was a wire sounding in Emden Deep with a 54-cm. core of red clay and a temperature and water sample from 10,068 m. In the same volume the commanding officer, Lieut.-Commander F. Pinke, describes the ship and her equipment, and the first officer, J. P. H. Perks, deals with the deep-sea anchoring gear, which was very successful. The surface observations of temperature, salinity, and density are discussed in detail by Dr. S. W. Visser.

The reports are well illustrated by charts and photographs, and the two volumes are a valuable contribution to oceanography.

ATMOSPHERIC TURBULENCE

Atmosphärische Turbulenz
Von Dr. Heinz Lettau. Pp. xi+283. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1939.) 18 gold marks.

The appearance of Dr. Lettau's book on atmospheric turbulence is a definite indication of the way in which the scientific study of the atmosphere is progressing. Many books have attempted, with varying success, to cover the whole field of what is known as meteorology, but so far there have been few books which have covered in detail one aspect of the subject. Lettau has done this for atmospheric turbulence. He has done it well, and this book will probably remain for some time the standard treatment of its subject. It gives all the essential mathematical treatment in a clear and concise form, and offers numerous comparisons with the facts of observation.

The names which recur most frequently are those of G. I. Taylor, W. Schmidt, L. F. Richardson, and of Prandtl and his disciples of the Göttingen school. The vast volume of detailed research in the field of aerodynamics published in recent years is not capable of direct application to the motions of the atmosphere, since these motions are complicated by varying roughness of the ground, and especially by varying degrees of vertical stability. The Reynolds number is therefore not in itself sufficient to determine what will happen in the atmosphere, and Lettau makes considerable use of the Richardson criterion, or the Richardson number,

$$Ri = \frac{g}{T}\left(\frac{\partial T}{\partial z} + \Gamma\right) \Big/ \left(\frac{\partial u}{\partial z}\right)^2,$$

where g is the acceleration due to gravity, T the absolute temperature, Γ the dry adiabatic lapse-rate, and u the wind velocity at height z.

Lettau gives a very readable account of the Prandtl theory of the laminar boundary layer, and of its extension to turbulent flow by von Kármán. He gives the logarithmic law of variation of wind with height, and summarizes concisely the extension of the theory to stable atmospheres by Rossby and Montgomery and by Sverdrup. The work of the last three has led to relationships which are in striking agreement with observations, but the physical basis on which it has been constructed is by no means clear. We should have welcomed fuller discussion of this basis.

Lettau gives the name 'planetary boundary layer' to the layer extending to a height of the order of 1 km. above the ground, at which the wind attains the value which gives a balance with the pressure gradient. The variation of wind with height within this layer can be discussed satisfactorily, but the transfer upwards of the daily wave of temperature change cannot be satisfactorily discussed on the basis of turbulence alone. Complications due to radiative transfer enter into this problem, and at the moment it is not possible to decide the precise nature of these complications. Moreover, the *austausch*-coefficient to be applied in this problem must be a function of height, and effectively of time of day.

Later chapters of the book, dealing with the dissipation of the energy of the air-streams by turbulence, and the general circulation of the atmosphere, describe problems which are in the main unsolved. The jump from what is normally regarded as an eddy to an entity as large as the cyclone or anticyclone appears to demand some justification. Dr. Lettau has rounded off his task by including a most valuable bibliography of 246 items, containing what appears to be a really complete list of the fundamental work in his subject.

D. Brunt.

SPECTROGRAPHIC ANALYSIS OF EAST INDIAN ROCKS

Contributions to the Knowledge of the Chemical Composition of the Earth's Crust in the East Indian Archipelago

1: The Spectrographic Determination of the Elements according to Arc Methods in the Range 3600–5000 A.; 2: On the Occurrence of Rarer Elements in the Netherlands East Indies. By Dr. W. van Tongeren. Pp. xi+181. (Amsterdam: D. B. Centen's Uitgevers-Maatschapij N.V.; London: H. K. Lewis and Co., Ltd., 1938.) 4.50 fl.; 11*s*. net; Part 1, separately, 3 fl.; 7*s*. net.

THE main object of the research described in this monograph was to ascertain the amounts of many of the less common elements, including certain members of the rare earth series, in the minerals and rocks of the East Indian Archipelago.

The first part deals with the method adopted. This consisted in preparing spectrographs of the pure elements over the range 3600 A.–5000 A., using standard mixtures of varying concentrations of the pure oxides with quartz. The apparatus is described in considerable detail together with the operating technique, and the effects of possible errors are carefully assessed. A full and valuable discussion follows on the relative intensities of the characteristic spectral lines, and detailed tables are appended.

Similar sets of spectrographs were obtained with the rock specimens and, by a process of comparison, estimates were made of the approximate contents of the different elements.

The second part discusses the results obtained from some three hundred specimens from the Netherland East Indies, including Java, Sumatra, Borneo and numerous other localities less well known to British readers. All the specimens were selected from those in the possession of the Geological Department of the University of Utrecht, and their authenticity was thus guaranteed. The data are valuable, but contain little of exceptional interest; one feels the author did not receive the luck he deserved. The rare earths were present only in minute amounts; vanadium varied up to a maximum of 0·3 per cent (pentoxide); germanium was not found, whilst indium occurred exclusively in zinc ore from Borneo.

The amount of work involved must have been great; the author is to be congratulated on having completed successfully so laborious a task.

J. Newton Friend.

THE NATURAL GEOGRAPHICAL REGION

By A. Stevens
University, Glasgow

THE most conspicuous geographical concept, the enunciation of which is associated with British geographical thought, is that connected with the phrase, 'natural geographical region'. In spite of much—rather sporadic—discussion, the concept remains obscure. Many who would like to employ the term are shy of it: they shorten it to 'natural region', and some limit the meaning of the epithet 'natural' to the physical, the inorganic; they distinguish the geographical region; they refer to economic, to 'human use' regions. All this hedging about terms is a sure indication of uncertainty of grasp as well as of diversity of view.

The term originally used by Herbertson was 'natural geographical region'. In most writing the middle word is dropped. Roxby says that a natural region is characterized by a particular set of physical conditions. But a uniform set of conditions is hard to find extended over a region of any considerable area. This is to be expected, of course: in a sufficiently small region one would find uniformity, or 'practical' uniformity, but in a large one it is necessary to search for unity within diversity. For large areas the 'dominant' physical condition becomes the criterion. Herbertson regarded climate as dominant in the characterization of his major natural regions of the globe, and this lapse in logic evoked serious criticism on the occasion on which he first propounded his views. The criticism was as immature as the thesis. No one, so far as we know, has entered on a systematic consideration of the geographical relevance of the various physical conditions, and an examination of this relevance would seem an essential preliminary to the establishment of dominance. Such occasional—and usually disingenuous—flirting with the question as occurs would indicate what is probably true, that any attempt in this direction is, in practice, hopeless.

The ultimate fallacy underlying this kind of thought or procedure is that it begins by assuming a duality, the physical and the non-physical, the human and the non-human, the natural and the artificial. It brings geography to the stage reached by the Schoolmen when they disputed between form and matter, matter and spirit, and questioned the possibility of knowledge. We are not concerned about absolute knowledge or complete knowledge, but only about a particular kind of knowledge and only about the attainable extent of that. We are concerned with physical and biological nature only in so far as it may be regarded as human environment and only with man in so far as he has demonstrable relationships with the environment.

Many will agree well enough with this last statement, but some of them, if not all, will insist that the method of geographical study is a synthesis or an integration.

Synthesis is not addition: it is a complex process for which there are no general rules. The chemist performs it successfully, but in special and individual cases. The mathematician is our best integrater. He may begin with a function of x and is as likely to end with a new branch of mathematics as with a reasonably simple new function of his variable. Neither of these magicians can operate with dissimilar things.

Something analogous to synthesis might be said to go on between man and his environment. If this analogy do not lead us astray once more, we might say that man is the synthetic influence. History is a spectator of the process, more or less blinding itself to everything but the time element. The geographer does not synthesize, because he cannot, but he also is a spectator of the process primarily interested in its development in space. Man must be looked at objectively by the geographer, and even his significant antics must be taken to be as natural as the physical environment. The natural geographical region is a result of what, for want of a better word, we may agree to call synthesis proceeding in Nature, under our eyes, but not by our voluntary action. There are two aspects of this synthetic product: the environmental aspect, essential to which is man himself, and the human aspect, which is much the same as to say the functional aspect, using the language of ecology.

The boundaries of the natural region (in our sense) are definite enough; which does not mean that they are necessarily simple or easy to trace. Where they are common to another natural region they are clearest. These boundaries indicate a state of equilibrium which may be stable but cannot be static. Change may occur in their position or in their condition. The most active normal change occurs when they are advancing unto unorganized country or relatively unorganized country. Such advances occur during colonization, even if that proceeds overseas. Their tendency is

---

* From the presidential address to Section E (Geography) of the British Association delivered in Dundee on September 1.

centrifugal, their actual development in space is limited by conditions. Organization by Rome was more or less regularly centrifugal, the advance of Germanism was eastwards. The boundaries of a natural region may be indifferent to natural (physical) boundaries. For an organism must have continuity in its medium, but continuity does not preclude variety. So the boundary of a natural region may cross a mountain range, partition a river valley, divide a coalfield; and it may be a better boundary for so doing. The time factor (*relative* time) is important here, for the question of stability, equilibrium, is a question of adjustment. It is no hardship to the economic structures concerned that France, Belgium, Holland and Germany share one coalfield. Their political frontiers antedate their industrial development. For the Romans the Rhine divided, for the Germans it unites, for the French it still separates. The flanks of a mountain range separate and are easily held; the passes connect.

For Herbertson with his analogies, man represented the nerves of a natural region. Not so: man is the living principle. The nature of that principle is not the subject we are called to study. The nervous system, if we must have analogy, is the means of communication in the widest sense; and the analogy is unduly narrow, for means of communication have nutrient as well as co-ordinating functions. In this place, it is true, we are less concerned with the former, for the purpose is to define the natural geographical region.

The unity of the natural geographical region is achieved, maintained and developed by organization, by cohesion, and this cohesion is attained and extended by intercourse, at first within and later beyond the region, provided the organic development is an indigenous growth. Since the fourteenth century the means of communication of the type associated with Western Europe has been undergoing continuous but uneven development. This development was stimulated by overseas discovery, but its progress gained speed of a new order in the nineteeth century with the concurrent development of railways and large-scale manufacture, and the acceleration has progressively increased until our day. In consequence the range and intensity of organizing ability and power have increased. The most satisfactory natural regions to contemplate, and to appreciate from geographical writing, had been fully organized and had their identity recognized before the modern era began. One has but to think of the French *pays*, and the deterioration of the work of such a master as Vidal de la Blache beyond the Paris Basin. No doubt the conservatism of the French countryside and the degree to which it was able for so long to preserve its archaic cohesions has made it a specially favourable field for regional studies. But traces of such a division of the country are not wanting in Scotland. Even in the Midland Valley names like Menteith and Lennox have not completely lost regional content, while names of regional significance are common enough north of the Highland Line. Elsewhere, access to extraneous sources of necessities and the means of establishing wider loyalties have obliterated local character and submerged local unity. What are the *pays* of the Rhone Valley? The speed of modern change has confused a great deal of thought.

There are minimum and maximum sizes for natural regions. The minimum is determined by the least extensive area, in extent and variety of natural endowment, capable of being organized and maintained, by its resources—physical, biological and human—for cohesion, sustenance and defence. The maximum is determined by the efficiency and range of means of communication. Both maximum and minimum vary in time.

Two types of organization must be distinguished and we shall call them conscious and self-conscious respectively. The former is primitive and appears less artificial. The latter is very modern. It is a development made possible by progress in general, especially in the knowledge of the possibilities of 'planning', and of the 'management' of environmental conditions; and in the development of means of communication in particular. The objective view of man excludes the possibility of regarding his actions as artificial. Some of them we may think ephemeral or capricious, but they have their source in the nature of man.

Natural regions must change in extent and otherwise with time, but the changes need not be continuous. At times of specially rapid change in human life the natural division into regions may almost suffer a revolution. But a true revolution, a sudden and catastrophic change, has occurred only in extra-European countries. In North America there must have been natural regions—or, if it is preferable, an analogue of a system of *pays*—of Indian times. The traces of these have been swept away, except what may be gleaned from such knowledge of tribal distribution as has persisted. We must distinguish natural regions of continuous and of discontinuous development.

Difference in scale would appear to be due to difference in topographic fragmentation—before due consideration has been given to the matter, so long as we consider the physical more fundamental and permanent. But it is neither. What is fundamental is relativity to man. Space, height, slope, areas at the time unproductive, all these represent difficulties in the problem of instituting and operating means of transport. At the present moment all of them within terrestrial limits have their price in time, labour, ingenuity and risk. If the price is commercially—and even strategically—still too high, the practical possibilities are still of commercial magnitude. It is only a hundred years since the scale of land transport began to approach that of water transport. Crossing the Alps by forces of great military significance was almost as great a marvel in the days of Napoleon as in those of Hannibal. It was less perilous than the invasion of Muscovy. What strength in men and material could be launched across these obstacles of space and altitude to-day? What 'fifth column' of 1940 can be certainly held at bay by the most powerful or secluded or distant people?

The 'natural geographical region' is an active organism. The size of a region growing freely is determined by the range of the means of cohesion. At a given time that range depends on the state of technical development of the community occupying the region in relation to the problems presented by the nature of the medium. If technical development is relatively stagnant, but territorial development is undisturbed, the 'organism' will expand up to boundaries which for topographic reasons, but also, it may be, on account of mere distance, are insuperable at the time. The state of equilibrium so reached in empty, barren or distant areas will be fluctuating. Improvement in the means of communication will produce an expansion of the organism, provided it is free to expand. In a 'new' country like the United States, that is, where the history of development is discontinuous, to the expansion of regional units are set the very wide limits compatible with modern means of communication.

Efficiency of communication may become uneven. Long-distance communication and bulk movement of commodities have undergone hypertrophy, while the more intimate contacts which produce 'neighbourliness' are weak. Very large areas may be fed, policed and defended. National organization is in a stable condition. In such conditions natural regions of the order of *pays* are never likely to develop, or, at least, to have more than a very ephemeral existence, until population densities are very different from their present condition. If regional unities of the nature of *pays* develop they will be on a vaster scale.

Some, at least, of the commonly recognized regional divisions of both Russia and the United States are represented, mistakenly, of course, as regions of monoculture with a characteristic crop produced under suitable climatic conditions. In fact, the corn belt is as much a region of mixed farming as the dairying belt and there is a great deal of pasture, largely unimproved, in both. The pressure of population on the land is low, and the region-community organism is far from the condition to which the ecologists apply the term 'climax association'. A state of equilibrium has not been attained. Two propositions follow from these considerations: the relation between the community is so loose that its activities do not fully reflect the conditions of the environment; the more intimate and less organizable contacts within the community are so indefinite that what we may call regional consciousness is rudimentary.

At the same time, what we have referred to as self-consciousness is of an advanced type. The 'human use' region, as usually distinguished, is an area of undeveloped economy. The natural geographical region emerges from chaos only when it has evolved to the stage at which it can be clearly recognizable as a synthetic whole with what the French would call 'personality'. When this stage of climax association has been attained, we are able to assess the relative significance of environmental (physical and other) factors; for this cannot be done satisfactorily except by using the nature and activity of the community as an index in the same way as the natural vegetation of a region has been employed as a climatic index. The climax condition, when it has been attained, is not necessarily permanent. It may change with greater or less rapidity in time, and the obvious reasons for change are human progress, chiefly technological, or the reverse, and exhaustion of resources, notably mineral resources, absolutely or due to alteration of values.

In the more westerly parts of Europe the centrifugal processes were propagated from a number of centres during the course of development to present conditions. Through a great deal of it something like climax conditions were reached before the railway era, and to these conditions belong the French *pays* and the German *Gau*. Such entities occur east of the Rhine only within the sub-Hercynian belt of dense population, and not throughout the belt. In the extreme west they expanded territorially up to natural limits which, being narrow, kept them small. Had these close natural limits been wider the *pays* would have been limited by the advancing peripheries of other organisms, and conflicts would arise which would be stilled only by coalescence into larger organizations by one of the methods known to history. Indeed the *pays* as we know it is no doubt a product of coalescence: as the smallest organism of the type, available for study, it may, merely for convenience, be regarded as indicating the practicable minimum. In areas more remote from the influences active in western Europe, and to the east in particular, slower progress in indigenous technology, greater obstacles to cultural importation, and correspondingly less rapid growth in population, absolutely and in relation to the extent of available territory, deferred to a comparatively recent date the attainment of the climax condition. The broader fragmentation of the country was a concomitant, but not at all necessarily the dominant determinant of the territorially larger organism.

Long before the railway era, France and Great Britain had achieved the more self-conscious organization of the nation-state by coalescences of various kinds. The process was less satisfactory in Spain. All three were able to relieve the unease to which increasing efficiency of means of communication made them liable by overseas adventure keeping step with that growing efficiency. The relief was illusory in the case of Spain. Germany had respite of a similar kind because she had her colonial area to the eastwards, and there she still has colonial spaciousness even within her present restricted bounds. In that direction also lie some of her deracinated offshoots, as others share the United States with ours and the French are to be found especially in Canada.

It is suggested that the European nation-state is a community occupying a natural geographical region as its immediate environment, because it is a natural growth limited by its geographical circumstances Not only so, it is an organic phenomenon so characteristically European in its genesis, to be found nowhere else in a state of mature development ; and therefore any European geography which failed to take account of it, indeed of which it was not the central object, ought to be unthinkable. The swing away towards the novelty of the physical region was a vain pursuit of novelty. If the real natural region for geographical study is as we have held, and if the nation-state-country organism of Europe is the achieved synthesis of European geography, then the region which is characterized by a set of physical attributes is, geographically, a misconception. For not only have many European States partitioned one of the main 'natural divisions' of the Continent among them by stable frontiers, but also it is unthinkable that any one community could develop that area as a whole and remain restricted to it. We refer to the North European Plain ; but there have been attempts enough to unify the 'Mediterranean' region, and there is sufficient division now and throughout historic time both there and in the Alpine region, where physical conditions favour severance rather than unity, to justify the same statement with regard to them. Physical conditions are neither more permanent nor more fundamental in geography than human. If in themselves they change less quickly than the characters of the living partner in the symbiosis, their significance and value change rapidly, even suddenly, and sometimes disappear We do not really believe in the permanence or significance we predicate For we approve and wish to maintain the further political subdivision which has taken place so recently in the North European Plain, we see reason in the demand for access to the sea or to a navigable river, but we boggle about allowing more than one nation access to a coalfield.

We see the countries of Europe as natural regions, natural because they exist as phenomena demanding study, demanding it with a special urgency in these days. Their territorial development seemed to have culminated before the War of 1914–18, and before the present unrest it underwent readjustment which seemed to offer some prospect of stability. We must look for objective explanations of failure. These States grew into contact with each other and organization permeated the whole of, or the more 'European' part of, the Continent. Not natural boundaries, but convergence of organisms set limits to expansion, especially for the later developed units, at a time when means of organization were developing rapidly. The proper scale of organization is no longer represented by the European nation-states but rather by the United States Disturbance of equilibrium shows itself by unrest in the newer countries which have not been disciplined by long confinement within narrow bounds and had their views of hegemony chastened by such a loss of territory and influence as the French suffered in the complete rape of an earlier empire, the British in the loss of their earlier colonies in America and by the development of increasing independence in the Dominions. For the countries east of France the region of colonial expansion has been continuous with the homeland ; the peoples of slower development whom they have replaced have been Europeans and have survived the disturbance of colonization. These countries do not appreciate the barbarity of applying in 1939 the moral principles applied by others in ruder times two centuries ago.

In Germany we can distinguish extensive areas over which the mean density of population is comparable to that of Great Britain But to the east, especially, the Reich has extensive areas of relatively recent occupation which we have called its natural colonial region, that which it has in fact exploited, whether of choice or of historical necessity. There the mean density of population is scarce half as great. On the other hand, the former kingdom of Saxony has proved capable of maintaining a mean density twice that of Great Britain. The urgency of any problem of *Lebensraum* is fanciful Straitness of living space is commonly relieved by more or less free movement of commodities from abroad, compensated by similarly free exportation. Voluntarily or involuntarily, Germany has to a large extent renounced this relief. The *malaise* seems by no means untreatable by other means

NEUTRONS AND RADIO-ELEMENTS AND THEIR BIOLOGICAL APPLICATIONS[*]

THE spontaneous radioactivity of a number of heavy elements has been known for a generation, but it is only within the last decade that attempts to induce radioactivity in stable elements have succeeded. Since the first successful experiments of Curie and Joliot, however, progress has been rapid and radioactive isotopes of the majority of the stable elements have been made. Now that powerful high-voltage plants are available, the quantity in which these artificial radio-elements may be obtained is in some cases comparable with the quantities of natural radio-elements which are available, and the artificial radio-elements are already beginning to compete with the naturally radioactive elements as sources of beta- and gamma-rays for physical purposes, and will probably soon be used on an appreciable scale for medical purposes for which radium is at present in use.

Economically, there is probably at present not much to choose between the use of radium and of artificial radio-elements, the interest charges on the capital invested in radium being of the same order as the costs of maintenance of a cyclotron. The special importance of the use of artificial radio-elements in biological experiments lies in the possibility of using active isotopes of elements already present in the organism and taking part in its metabolism.

There are at present two methods of producing artificial radio-elements in quantity, the first being the direct bombardment of inactive material with protons, deuterons or alpha particles, and the second the activation of inactive materials with slow neutrons, the latter being produced by the slowing down in paraffin or water of neutrons generated in some reaction such as the bombardment of deuterium or beryllium with deuterons. Either method thus starts with the production of a beam of fast charged particles. The direct way of obtaining such a beam is to generate the requisite high voltage and apply it to a vacuum tube in which the ions are accelerated. This was the method used by Cockcroft and Walton, and the Cavendish Laboratory now has a generator of the Cockcroft and Walton type operating at two million volts. Apparatus of this type, in which the full voltage is applied to the accelerating tube, would become very cumbersome at still higher voltages, on account of the large clearances necessary to prevent spark-over, and further extension of this method is likely to proceed along the lines of enclosing the apparatus in a high-pressure or oil-filled tank. When considerations of finance limit the voltage to a million or less, however, it is the best type of machine, since the fact that ion currents as high as one milliampere may be obtained counter-balances to some extent the diminished disintegration yield at these relatively low voltages.

Dr. J. Read and Dr. L. H. Gray have installed a machine of this type at the Mount Vernon Hospital, London, producing neutrons by the D + D reaction and operating reliably at 300–400 kv. with ion currents up to 900 microamperes. This plant has so far given an output of neutrons equal to that produced by 30 curies of radon plus beryllium, which is sufficient for investigating the more sensitive biological reactions of radiation. It was built at a cost of £600, and has been operated for two years at the very modest figure for maintenance of £80 per annum, both figures being of the order of one tenth the corresponding costs for a large cyclotron. The deuterons are drawn from a low-voltage arc, and after acceleration fall on the target, which is at earth potential. The target is a film of heavy paraffin wax deposited on a copper plate water-cooled on its underside; the material to be irradiated can be brought to within 1 cm. of the focal spot. The bombardment of the paraffin wax rapidly causes chemical changes to a less saturated hydrocarbon of only half the deuterium content, with consequent loss in neutron output. After the initial fall, however, the output remains constant for some months of use.

When particles of very high energy are required, the method *par excellence* is the cyclotron developed by Prof. E. O. Lawrence, in which ion energies of millions of volts are attained by repeated impulses of 100 kv. or so given twice per revolution as the ions execute a spiral path between the poles of a large electromagnet. The largest cyclotron at present in operation is that recently completed at Berkeley, California, and with this machine deuterons of 18 Mv. and alpha particles of 38 Mv. have been obtained. The neutron intensity from this machine is adequate for therapy at distances from the target of the order of 1 metre.

---

[*] Based on a discussion in Section A (Mathematical and Physical Sciences) of the British Association, which took place on August 31 and September 1, those taking part being Dr. J. Lawrence, Dr. W. B. Lewis, and Dr. J. Read and Dr. L. H. Gray.

With the smaller Berkeley cyclotron, which gives particles of about half this energy, a considerable amount of biological work has already been done. The effect of neutrons in killing mice, Drosophila eggs, bacteria and fern spores, in producing chromosome abnormalities and in inhibiting growth in wheat seedlings has been compared with similar effects produced by X-rays and gamma-rays. The effects are in general qualitatively similar, but suggest that in most of these cases the biological effect per ionization in the tissue is greater for neutrons than for X-rays. That this is not a general phenomenon is shown, however, by the experiments of Timoféeff-Ressovsky and Zimmer, who find that neutrons are somewhat less effective per ionization than X-rays in the production of gene mutations in Drosophila. The investigation of the dependence of the biological efficiency per ionization upon the specific ionization of the ionizing particle is one of the most promising methods of investigating the mechanism of the biological action of radiations.

Following the experiments on animal and plant material, the treatment of cancer patients with neutrons has now begun at Berkeley. A satisfactory degree of collimation of the neutron beam, which is essential for cancer treatment, has been obtained by the use of a lead-lined channel in a water tank. It is not yet known how successful the use of neutrons will be in the treatment of cancer, compared with X-rays. Encouraging therapeutic results have, however, already been obtained in another direction, namely, in the treatment of leucæmia by the oral administration of radiophosphorus. A marked fall in the white cell count and improvement in the condition of the patient follows the dose, which is repeated at intervals when called for by a rise in the white cell count.

Numerous uses for the artificial radio-elements in experimental biology have already been found, particularly in investigating metabolic problems. The admixture of a small quantity of a radioactive isotope with a larger mass of inactive atoms serves as a tracer for these atoms, and enables one, for example, to find out what proportion of a particular element administered orally is excreted immediately, and what proportion is taken up by each organ. If sodium chloride containing some radioactive sodium is swallowed, sufficient will find its way into the hand in ten minutes to affect a Geiger counter shielded from the rest of the body. Injected intravenously in one arm, its presence can be detected in the other arm some twenty seconds later, an experiment having possible applications in the investigation of circulatory disorders.

THE HABITS OF SALMON

In recent years, intensive investigation of the life-history and habits of salmon and trout has been carried out in all the countries where the species are of importance. The results of the investigations were recognized by a symposium on salmon at the summer meeting of the American Association for the Advancement of Science in Ottawa in 1938, and by a morning devoted to the subject at the recent meeting of the British Association at Dundee.

Salmon spend from one to five, and normally two or three, years as parr in fresh water. Here recent investigations have shown that growth is not entirely seasonal but that, contrary to expectation, a marked slowing down, if not cessation, of growth occurs in August when conditions might normally be expected to be favourable. This coincides with the experience of trout anglers, to whom August is often anathema, and of fish farm operators who, however, recognize a close connexion between water temperature and food intake and digestive activity. Mr. K. R. Allen has already noticed this fact and, at the Dundee meeting, Dr. K. Carpenter argued that the diminution of growth and, concomitantly, of the intake of food organisms, was directly associated with a marked decrease in the number of organisms available in the streams.

It has long been recognized that in their second year, or for those that remain so long, in their third autumn, certain male salmon parr may become sexually mature and may spawn with adult females. That the spermatozoa of these precocious fishes functioned successfully was shown at least fifty years ago. Prof. J. H. Orton and Mr. J. W. Jones have recently pointed out that a quite considerable proportion of the male parr may be ripe, and Mr. Jones stated at Dundee that by dissection it is possible to trace during the smolt stage in the following year those which had spawned some six months earlier. The significance of this precocity is not yet understood. It is unlikely that it forms an important contribution to the continuance of the stock, but it is quite possible that it may affect the length of life spent in the sea. The fish concerned may return after a shorter, or longer, period of sea feeding than those which did not spawn in the parr stage, among which are included all the females. The present writer, however, recently examined a female salmon which had apparently become voluntarily landlocked in a long and deep Scottish loch, and in the course of its seven years of life had spawned at least twice.

Once the parr become smolts and descend to the sea they are lost in the widths of the ocean, but something may be learnt of their routes of travel when, their feeding finished, they touch the coast and continue onwards to fresh water. From Ardnamurchan Point on the west coast of Scotland, the salmon either stay in the locality or travel south, it may be as far as the Liffey in Eire or the Conway in Wales. But, from only thirty miles farther north at the island of Soay off the south coast of Skye,, and then up through the Minch to Cape Wrath, the majority of fish which strike the coast do not belong to the neighbouring rivers and do not travel south. They go north to Cape Wrath, along the north coast and, in many cases, down the east coast. From the middle area (near Bergen) of the outer island belt on the Norwegian coast, the fish spread both north and south, some to very considerable distances: one fish travelled some 1,600 miles from the place of marking before it was recaptured on the inner shore of the White Sea. From another marking station near the North Cape, on the other hand, Prof. Knut Dahl and Dr. Sven Somme have found that the fish made no long migrations southwards, but many were re-taken, like the salmon marked in the north-west of Scotland, to the eastwards. They travelled along the north coast of Sweden, Finland and Russia as far as the eastern limit of *Salmo salar* in the River Petchora. On the other hand, the movements of the salmon captured, marked and released at the east end of the north coast of Scotland, on the Scottish east coast and close to the mouths of the Norwegian fjords, are limited close to their original locality or the immediately neighbouring rivers.

The inference to be drawn from a consideration of all the marking experiments and other relative data is that the feeding ground for the European salmon is not in the North Sea. The movements revealed are not inconsistent with the probable journeys of fish from an area some distance to the west or north-west of the British Isles. It would, further, seem probable that the majority of the fish going to the rivers flowing into the North Sea enter that area by the open channel between Shetland and Norway, and some possibly by the Fair Island Channel, but relatively few through the Pentland Firth.

In spite of the distances which many of the marked fish travel, it would appear that they do so not in random wanderings but in the course of a definite journey to their native river. Every angler and net fisher of experience knows that different rivers contain salmon of different character. Some rivers, for example, have salmon early in the season, and some only later in the spring and summer; some rivers contain essentially grilse, others chiefly older and larger salmon. Such differences might be ascribed to selection by the fish on account of physical characteristics of the river itself. But Mr. P. R. C. Macfarlane stated that other evidence such as the lengths of the fish at the end of each year of life, as shown by measurements of the scales, the condition factor (the relationship of weight to length), and the type of scale growth, points to the existence of separate biological communities in each individual river. As cases in point, a salmon marked in Scotland and recaptured in Norway had scales with parr growth of a very characteristic Norwegian type, while others marked on the Norwegian coast similarly showed parr growth exactly comparable with the known type of the Scottish rivers in which they were recaptured

W. J. M. M.

OBITUARIES

Dr. G. J. Robertson

DR. GEORGE JAMES ROBERTSON, senior lecturer in chemistry in the United College, University of St. Andrews, died suddenly on September 5 at the age of forty-one years. A son of the late Mr. James Robertson, head master of Colinsburgh School, Fife, he entered the University of St. Andrews from the Madras College, St. Andrews, in October 1916. He undertook military duties soon afterwards, and held a commission in the Gordon Highlanders, 51st Highland Division. He was on active service in France from September 1917, and in March 1918 he was taken prisoner at Cambrai and interned in Germany until the end of the war.

Robertson returned to the University of St. Andrews in 1919, and graduated M.A. (1921) and B.Sc. with first-class honours in chemistry (1922). He held in succession a Carnegie Research scholarship, fellowship, and teaching fellowship in the Chemistry Department at St. Andrews. In 1924 he was awarded the degree of Ph.D. for a thesis entitled "Investigations on Cellulose". Since 1927 he had been senior lecturer in the Department, and in this capacity he carried out and directed a considerable amount of research work in carbohydrate chemistry. In 1936 he was awarded the degree of D.Sc. for a thesis entitled "Walden Inversions in the Sugar Group"; this thesis also gained him the Sykes Medal for outstanding merit. His investigations, most of which were published in the *Journal of the Chemical Society*, dealt largely with the interconversion of simple sugars through anhydro-derivatives and the problem of the natural formation of lactose, glucosamine and allied substances.

Courteous and considerate to his colleagues and students, Robertson has been described as "an excellent teacher endowed with unusually fine powers of expression and easy fluency". His military training enabled him to render valuable services to the University O.T.C. throughout his period as a member of the University staff. He leaves a widow and two sons of school age.

Mr. H. Young

BY the death of Mr. Henry Young on September 23, the Royal Institution loses its last surviving link with Faraday. Mr. Young used to say that Faraday was a frequent visitor to his home, and as a child he must have seen him, though he was too small to remember meeting him.

Mr. Young was engaged as assistant in the library of the Royal Institution in 1879 and ten years later was appointed assistant secretary and keeper of the library, which double post he held until his retirement in 1929. He was also assistant secretary of the Davy Faraday Research Laboratory from its foundation in 1896. At their meeting on December 2, 1929, the managers elected Mr. Young a member of the Royal Institution, and at the general meeting on the same day Sir James Crichton-Browne, on behalf of the members, presented him with a silver rose bowl and a cheque as a mark of their appreciation of his long services. After his retirement, he was a frequent visitor to the library which had been under his care for so many years. Mr. Young compiled valuable bibliographies of the scientific work of Tyndall and Dewar, under both of whom he served. Afterwards, as librarian to the Duke of Bedford, Mr. Young was fortunate in finding a congenial and not too strenuous occupation for his leisure hours in the library at Woburn Abbey.

Modest and retiring in disposition and of a genial nature, Mr. Young had a remarkable knowledge of the history and inner working of the Royal Institution, which he loved and to which so many years of his life were devoted.

WE regret to announce the following deaths:

Dr. J. D. Comrie, lecturer in the history of medicine, University of Edinburgh, and president in 1927 and 1930 of the Section of the History of Medicine of the British Medical Association, on October 2, aged sixty-four years.

Prof. Harvey Cushing, For. Mem. R.S., emeritus professor of neurology in Yale University, known for his work on the surgery of the brain, on October 7, aged seventy years.

Dr. Heinrich Karny, formerly of the Botanical Garden, Buitenzorg, Java, an authority on the Orthoptera, on August 7.

Prof. Charles Peabody, formerly curator of European archæology in the Peabody Museum, Harvard University, on August 17, aged seventy-one years.

NEWS AND VIEWS

Prof. A. McKenzie, F.R.S.

AT a graduation ceremony held on October 6 in the Old Parliament Hall of the University of St. Andrews, and presided over by Sir James Irvine, principal and vice-chancellor of the University, the honorary degree of LL.D. was conferred, amongst others, upon Emeritus Professor Alexander McKenzie, professor of chemistry in University College, Dundee, from 1914 until 1938. In presenting him for the degree, Prof. John Read, the present occupier of the chair of chemistry at St. Andrews, said that McKenzie, when he was appointed to the chair of chemistry in University College, Dundee, in 1914, was already well known as a distinguished graduate of the University of St. Andrews, with a brilliant record of original research, begun with Purdie at St. Andrews, continued with Marckwald at Berlin, and extended independently in London and Birmingham. His later researches, together with those of his many collaborators, published during his twenty-four years at Dundee, are familiar to chemists all over the world; for he was a skilful chemist and philosophic thinker of international renown, who has brought light into many of the dark places of stereochemistry. His pioneering researches with the Grignard reagent; his work on asymmetric synthesis and on the migration of organic radicals; his isolation of optically active benzoin: these, and other achievements, are characterized by a subtle elegance and a rare combination of fastidiousness and delicacy. In attacking the refined secrets of the organic molecule, he discards the ponderous weapons of men of grosser mould for the light rapier of the "chymicall Artist". By his brilliant and untiring investigations, McKenzie has brought renown to his university and his college; by his stimulating teaching he has inspired successive generations of his students; by his wise counsel he has aided his colleagues of Court, Senatus, and Faculty; and by his gifts of sympathy, kindliness, and understanding he has gained the esteem and affection of all.

Mojsisovics von Mojsvar (1839–1907)

On October 18 occurs the centenary of the birth of the distinguished Austrian geologist and palæontologist Johann August Georg Edmund Mojsisovics von Mojsvar. The son of a surgeon, he studied law at Vienna, taking his doctor's degree in 1864. Three years later he entered the Geological Institute with which he was connected until his retirement in 1900. From 1892 until 1900 he was vice-director of the Institute. His first geological tours were taken in the Salzkammergut with his famous teacher Suess. For more than thirty years he devoted much attention to the Austrian Trias and among his principal writings was his work entitled "The Dolomite Reefs of South Tyrol" published in 1879. He was instrumental in furthering the systematic collection of fossils from the Eastern Alps, and his own work on the Cephalopods, said von Zittel, "is an achievement of permanent value and general scientific interest", conferring a boon on Alpine geology and zoological knowledge. For many years, with Melchior Neumayr (1845–90) he conducted the *Beiträge zur Palæontologie und Geologie Oesterreich-Ungarns*; and he assisted in founding the Austrian and German Alpine Clubs. He died at Mallnitz on October 2, 1907.

William Morrant Baker (1839–1896)

Mr. William Morrant Baker, a prominent London surgeon of the pre-aseptic era, was born on October 20, 1839, at Andover, where he was educated at the Grammar School. He received his medical training first by serving as an apprentice to a local surgeon and later entered as a student at St. Bartholomew's Hospital, London. He obtained the qualification of M.R.C.S. in 1864, and became F.R.C.S. in 1867. Between the years 1862 and 1892 he obtained a number of appointments at his hospital, including those of demonstrator of anatomy, lecturer in physiology, surgeon to the skin department, casualty surgeon, assistant surgeon and full surgeon. He was also surgeon to the Evelina Hospital for Children, examiner for the Royal College of Surgeons and of the Universities of London and Durham, and associate editor of Kirke's "Handbook of Physiology". He retired from the staff of St. Bartholomew's Hospital in 1892. Under the term of "Baker's cysts" his name is attached to hernial protrusions of the synovial membrane of a joint through an aperture in its fibrous capsule. He also invented a flexible tube of red rubber for tracheotomy which is named after him.

Animals during War-time

The importance of safeguarding animal life under war conditions has been fully realized by the Government and a useful and effective scheme has been worked out. The Home Office has appointed a National Air Raids Precautions Animals Committee. In each district or danger zone, all the local veterinary surgeons and the animal clinics and depots of the local animal welfare societies are co-operating under regional organizers appointed by the Home Office. These regional organizers are usually qualified veterinary surgeons. The Government A.R.P. Handbook No. 12 dealing specially with animals has been widely circulated, and the People's Dispensary for Sick Animals purchased 100,000 copies for free distribution to people who cannot afford them.

In a circular just issued to its members, the Zoological Society of London directs attention to the "many grave problems" war conditions have brought to its collections, which include a serious drop in revenue. Drastic staff and general expenditure reductions have been made; the aquarium has been closed owing to the danger of air-raids breaking the glass tanks, and the reptile and tortoise houses are being closed to avoid the expense of heating them. A beginning has been made in the destruction of animals, and substitute foodstuffs not required for national needs are being used for the nucleus collection it is hoped to preserve. The North of England Zoological Society has so far withheld the destruction of its collection at Chester Zoo, and under an 'adoption' scheme has already had the cost of upkeep of many of its animals promised under weekly subscriptions, some for the duration of the war, from animal-lovers over a wide area. It has recently accepted a large donation of waterfowl and geese from Mr. S. P. B. Frame, and a foreign bird collection. It has used its educational value by admitting thousands of evacuees free. Dudley Zoo has offered most of its animals for sale.

National Rat Week

In view of the serious depredations on food stocks by rats, the Ministry of Agriculture and Fisheries considers that the annual Rat Week should be held this year notwithstanding the war. The Week will begin on November 6, and the Minister asks everyone to make a special effort during the week to destroy any rats on their own lands and premises and to take all possible steps towards securing concerted action against these vermin. The Rats and Mice (Destruction) Act, 1919, places an obligation upon every occupier of 'land', which term includes buildings on or under land, to take steps to destroy rats and mice on the property which he occupies and to prevent such property from becoming infested. The Ministry's Advisory Leaflet No. 49—"The Destruction of Rats and Mice" contains information and advice on methods for dealing with rats. A copy may be obtained free of charge from the Offices of the Ministry, 10 Whitehall Place, London, S.W.1. Further information on the subject of rats is contained in Bulletin No. 30, "Rats and How to Exterminate Them", copies of which are obtainable through any bookseller, or direct from H.M. Stationery Office, York House, Kingsway, London, W.C.2, price 6*d*. (7*d*. post paid).

First Aid Posts and Workers

A very useful "Memorandum for the Guidance of Medical Officers and other Personnel at First Aid Posts" has been issued by the Ministry of Health (H.M. Stationery Office. 3*d*. net). The functions and staffing of first aid posts, and the duties of first aid workers, are first dealt with, after which general directions are given for the use of dressings and treatment of injuries and burns. Injuries and their first aid treatment are then dealt with in detail of various regions of the body. Finally, some valuable hints are given for the treatment of patients who may be suffering from fright, fear or nervous shock. The appropriate opium dosage to be used for cleansing burns and scalds is given in an appendix.

Psychiatry in the Punjab

IN his chairman's address at the inaugural meeting of the Indian Division of the Royal Medico-Psychological Association (*J. Ment. Sci.*, 85, 381; 1939) Lieut.-Colonel C. J. Lodge Patch gives a striking account of the inhuman treatment of the insane in India which has persisted down to the present day. During the last hundred years, though there have been flashes of intelligence, interest and humanity in the 'forties, 'fifties and 'sixties associated with the names of Honigberger, Smith and De Renzy, there have been frequent returns to a state of almost primeval darkness. On his appointment as medical superintendent of the Punjab Mental Hospital in 1922, Colonel Patch found a deplorable state of affairs. Nearly all the male patients were allowed to go about stark naked, handcuffs and fetters were applied on little or no provocation, and the patients were living in a reign of terror. His first act was to collect two hundredweight of handcuffs and send them in a bullock cart to the central jail. His next was to dismiss a swarm of undesirable attendants, and then to remove the bolts and bars which gave the hospital the aspect of a prison. Within the last few months a new hospital has been built to Colonel Patch's designs on modern lines and not containing a single bar, grill or grating. Throughout the whole of India, abuses in the treatment of the insane still exist, as is shown by the fact that Colonel Patch has admitted to his hospital hundreds of patients with scars of beatings, blisterings, bleedings and other brutalities administered to drive out the devil supposed to have taken possession of the madman's mind. There is therefore much that can be done in India by spreading knowledge of the nature, prophylaxis and treatment of insanity.

Dust and Disease

IN his inaugural thesis (*Thèse de Paris*, No. 522; 1939), Dr. André Assémat remarks that the inhalation of dust is the cause of various lesions in the respiratory system, but that the gravity of the pulmonary involvement is mainly due to its effect on the general condition. He adopts Teleky's classification of the modes of action of dust in the following eight groups: (1) A microchemical action giving rise to characteristic lesions, especially in the case of silicosis and asbestosis. (2) An action which does not produce any changes in the lung until after intense and prolonged inhalation, as in the case of coal and non-siliceous mineral dust. (3) An action affecting the respiratory tract rather than the lung, as in the case of coarse wood dust, textiles and cereals. (4) A carcinogenic action caused by the dust of chromates, nickel and radioactive substances. (5) A sensitizing or allergic action. (6) A chemical action favouring the development of inflammatory processes. (7) An infective action when the dust is associated with micro-organisms and fungi, etc. (8) An intoxication of the system, as in the case of manganese. Apart from its own action, dust may be an aggravating factor in the course of lung disease. The tuberculosis problem is closely connected with that of pneumoconiosis, and especially silicosis, which always aggravates the prognosis. Occupational diseases due to dust represent an important cause of temporary or permanent incapacity for work and therefore have a bad effect on the general activity of a country. Before studying the means of repairing the damage done by certain forms of dust, it is important to secure the prevention of these diseases by the use of all the methods capable of protecting the worker, such as interception of the dust at its source, ventilation and the wearing of masks. The medical officer should play an important part in the engagement of workers and should reject any who suffer from pulmonary disease, especially tuberculosis, as well as those with a defective naso-pharynx. After enrolment, the workers should undergo periodical examination, and skiagrams should be taken and kept for future reference.

Destruction of Rabbits

IN days of war, our stock of wild rabbits has value as a food-supply, but the experience of the War of 1914–18 was that the absence of game-keepers and rabbit-trappers permitted an excessive increase; and their food value did not balance the damage to crops they did. Accordingly, in 1917 it was found necessary to legislate for the prevention of damage by rabbits, the emergency legislation being repealed in 1921. The experience of the last war is likely to be repeated in the present conflict, but now the situation is more favourable from the nation's point of view, since there has been on the statute book since July of this year a Prevention of Damage by Rabbits Act, which offers facilities for dealing with the rabbit pest. For the successful carrying out of the obligations of the Act, the Universities Federation for Animal Welfare has published a revised and enlarged edition of its "Instructions for Dealing with Rabbits". This 20-page pamphlet gives much information about rabbit-proof fencing, fumigation, long-netting, ferreting, shooting, catching with dazzle-light (an impracticable method under 'black-out' conditions), catching in enclosures, and it naturally omits reference to the less humane method of the steel-trap against which the Federation has waged constant warfare. The pamphlet is a handy and reliable guide to methods of keeping down rabbits, and its value is increased by the inclusion of the text and a brief explanation of the provisions of the new Act. Single copies of the pamphlet may be had free on enclosing a stamped and addressed quarto envelope to UFAW, Gordon House, 29 Gordon Square, London, W.C.1, or larger quantities will be supplied at cost price (3*d*. each).

Tuberculosis in Cyprus

THE final report on investigations on tuberculosis in Cyprus, conducted by Dr. N. D. Bardswell for the National Association for the Prevention of Tuberculosis, has been issued (*Tubercle*, 20, 97, 165; 1939). An intensive study of the disease in the Larnaca district indicates that actually the incidence of pulmonary tuberculosis is low, 140 cases in a population of 42,000, with an average death-rate of 0·69 per 1,000 population. There is little non-pulmonary, and no bovine, tuberculosis, and the disease in distribution is sporadic and largely familial. These figures fall far short of estimates by the Cyprus authorities prior to the National Association's mission. The Cypriot has a high resistance to the disease, which appears to be transmitted to an unusual degree from one individual to another. This is dependent upon the national habits; families almost invariably live and sleep in one room, and, in winter, houses are always completely closed at night. The standard of living of the people is low and poverty almost universal, though the nutrition of the people appears to be adequate. Tuberculosis in the Larnaca district and in Cyprus generally, though low in incidence and benign in type, is difficult to control owing to the general conditions existing in the island. The most effective measures would be the establishment of dispensaries in various parts of the island, and of a small sanatorium for education and treatment of the more favourable cases. A comprehensive tuberculosis scheme on these lines is in process of organization.

The Government Laboratory

REPORTING on the work of the Government Laboratory for the year ending March 31, 1939, the Government Chemist, Dr. J. J. Fox, surveys the scientific work which is carried on at the laboratory in Clement's Inn Passage, at the Custom House, London, at the chemical stations at certain seaports, at the Geological Survey Museum, at the Office of Works Stores, and at the War Office Supply Reserve Depot, Deptford. Substantially more than half a million examples were dealt with, although the number was about seven thousand less than in the preceding year. As is well known, these samples are drawn from an extremely wide range of products; foodstuffs and medicinal substances are tested for purity and for conformity with specification, beverages, oils, etc., are assessed for duty, metals, coal, rubber, cement and many other materials purchased by Government Departments are submitted to examination, and expert assistance is rendered in the detection of fraud. In addition, the Government Laboratory makes a very substantial direct addition to chemical science as a result of the many investigations which its normal work necessitates, of its participation in international oceanic research, of the pure research work which is constantly in hand, and of the personal contributions of members of the staff to the deliberations of various councils and committees which deal with scientific and industrial problems.

Farm Electrification

THE recent trends in research and development which characterize farming to-day are discussed in an article contributed to the *Electrical Review* of September 15 by A. G. H. Dent. The types of farming in Great Britain are now very varied; there are few large fields of wheat and barley; but the average farm produces dairy produce, poultry, market gardening and livestock and a certain amount of grain for consumption by the livestock. The electrical authorities giving a supply to some areas have little difficulty in showing farmers that they can get an economic return by using electricity, but in other areas the problem is a difficult one. The cost of giving facilities to a farm at some distance from the supply may be high, and there may be little evidence of an annual return which would justify the authorities in giving these facilities. Notwithstanding drawbacks, the development of rural electrical supply in Great Britain has reached a position comparable with that in any other country. We are glad that the British Electrical and Allied Industries Research Association is now examining the standardization problem of supply to isolated farms and is putting into action schemes of experiment and research applied to various farm processes. These schemes cover both agricultural and horticultural experimental work. The plans of research are both technical and economic in character. They aim at establishing the best and most practical technique of doing a farming operation, the most suitable apparatus for the job and the proper method of application. On the economic side, the aim is to find the exact cost of the electrical method in comparison with other methods and to find out what modifications of practice are desirable to obtain the maximum efficiency from the electrical method.

Science and Fruit Growing

RECENT issues of the *American Fruit Grower* contain several brief announcements of successful applications of science to the fruit-growing industry. The issue for May describes the use of solidified carbon dioxide in addition to the usual wet ice for the cooling of strawberries during transit from Louisiana to New York. The new method saves 25–40 per cent in refrigeration costs, and has the additional advantage that the gas resulting from evaporation enhances the keeping quality of the fruit. Prof. M. A. Blake of the New Jersey Experiment Station shows, in the same issue, that stout vegetative growth of the apple shoot is more to be desired for fruit bud production than long slender shoots. The formation of such buds depends upon the presence in the wood of more starch and sugars than are utilized in growth and respiration. This excess cannot be stored while succulent or rapid growth continues, but only after growth in length is arrested. R. J. Cohen, in another direction, has used the oil from grapefruit seeds as a mordant in textile dyeing, whilst Dr. W. M. Neal has tested the residue from such seeds as a possible food for livestock. The

July number contains a brief account of the investigations of Dr. E. N. Cory of Maryland into the insect pests of chestnut, hazel nut and walnut trees. A new departure in control practice lies in the use of synthetic cryolite and barium fluosilicate, applied as a spray or dust against the walnut husk maggot. A fascinating study of codling moth damage has been made by John A. Callenbach of Wisconsin University. He found that such injury was greatest near dusty roads. Dust upon the fruit prevented the proper covering of spray fluids, and it has been shown that roads can be rendered dustless by the use of calcium chloride spread upon the surface.

Check-Lists of Forest Trees in Ceylon

THE Imperial Forestry Institute at Oxford has been issuing a series of check-lists of the forest trees and shrubs of the British Empire, under the editorship of Dr. J. Burtt Davy and Mr. A. C. Hoyle. The fourth of the series is entitled "Draft of First Description Check-List for Ceylon". These monographs are chiefly designed for the use of forest officers. So far, although there has been a forestry department in Ceylon for more than half a century, all the forest officer has had to consult is Trimen's "Handbook of the Flora of Ceylon", consisting of six large tomes, published some thirty-five years ago, with a supplement by Alston issued in 1931. The Check-List in question has been compiled from published records and herbarium material. Some 832 species of trees and shrubs are included. In addition, a list of exotic conifers introduced into Ceylon, comprising twenty-five species (genera, Callitris, Cupressus, Juniperus, Widdringtonia, Abies, Picea, Pinus, Pseudotsuga, Sequoia, Taxodium, Tsuga), is included in an appendix. There is also an indispensable list of vernacular names.

Science Progress

THE editors and publishers (Messrs. Edward Arnold and Co.) of *Science Progress*, founded by Sir Ronald Ross in 1907, announce with regret that the October number will be the last to appear for the present. The purpose of this well-known quarterly review is to record recent advances in pure science and to publish articles by those who have played a leading part in such work; as research of this kind is bound to be seriously diminished in war-time, it has been reluctantly decided to suspend publication until conditions are more favourable.

The Faraday Society

THE Faraday Society will continue its normal activities so far as possible during the war. Roughly 60 per cent of the members are normally resident in the United Kingdom, and 40 per cent overseas, including 8 per cent resident in German territories. The Society's services to its members consist mainly in the regular publication of the *Transactions* and in the provision twice yearly of meetings of such importance that it is worth while coming from all parts of the world to attend. This latter activity must obviously be suspended for the time being, but it may be possible to organize 'general discussion' in writing, and to publish the final record. The papers which were to have been discussed in Cambridge during September 25–27 will be published early in 1940, and it can then be seen whether a written 'discussion' is practicable and useful. The *Transactions* will appear regularly every month and the policy of publishing all papers as soon as they have been refereed and accepted will be continued. It is hoped, moreover, that the flow of papers from overseas will continue to increase. It should be emphasized that, though the *Transactions* are printed in English, the Society will, if desired, bear the cost of translating any accepted paper which may be written in another language. The usual arrangements for exchange of membership with the Electrochemical Society, the Nederlandsche Chemische Vereeniging and the Société de Chimie Physique will be continued for 1940.

Institution of Electrical Engineers

IT has been decided by the Council that as many as possible of the activities of the Institution of Electrical Engineers should be carried on during the period of the war in the same way as hitherto, and that the library and headquarters of the Institution should remain for the time being in the present building at Savoy Place, W.C.2. All meetings that were to have been held in London for the reading and discussion of papers have been cancelled. Most of the local centres have also suspended their programmes. As an alternative to meetings, a complete list of the papers that were to have been read will be issued to members at the end of October, and advance copies can be obtained on application to the Secretary. Copies of the presidential address, which was to have been delivered by Mr. Johnstone Wright at the opening meeting in London on October 26, will be circulated. As already announced, the associate membership examination arranged for November next will take place, and it is hoped that it will be found practicable to continue to hold this examination at the usual intervals in future.

The Linnean Society

THE Linnean Society of London has decided to carry on its functions at Burlington House, London, during the war, so far as is possible. The rooms of the Society will be open from 10 a.m. until half an hour before sunset. Three meetings have been arranged to be held before Christmas, on October 26, November 9 and 23, beginning at 2.30 p.m. The Council of the Society is particularly anxious that the rooms of the Society shall be maintained as a central meeting place for biologists for the purpose of both formal and informal discussions.

British Psychological Society

THE work of the British Psychological Society is being carried on at 20 West Avenue, Hendon, London, N.W.4, where correspondence and inquiries should at present be sent. Meetings of the Society have been suspended, but it is hoped to hold the annual general meeting on December 9, at 2 p.m.

Imperial College of Science and Technology

The following Departments of the Imperial College of Science and Technology will reopen on October 17 for the categories of students mentioned: Engineering, Mathematics, Physics (second and third years and postgraduates); Chemical Engineering, Geology and Oil Technology (third and fourth years and postgraduates); Mining, Mining Geology and Oil Technology (second year). In addition, the Chemistry Department will open on October 24 for second and third year and postgraduate students, and it is hoped that the postgraduate course in aeronautics may be reopened at an early date. The third and fourth year mining and mining geology students are at Camborne, and the third and fourth year metallurgy students at Swansea. Such students of biology as can be accommodated will assemble at the College Biological Field Station at Slough. It has not been found possible to continue the first year work leading to the Intermediate B.Sc. and B.Sc.(Eng.).

Colonial Service: Recent Appointments

The following appointments and promotions have recently been made in the Colonial Service: P. A. Gething, agricultural officer, Nigeria; R. Smith, superintendent of agriculture, Gold Coast; W. S. Biggar, veterinary officer, Northern Rhodesia; J. B. Randall, veterinary officer, Uganda; J. I. Taylor, veterinary officer, Northern Rhodesia; D. G. White, veterinary officer, Tanganyika Territory; W. L. Ricketts, personal assistant to the Director of Agriculture and Fisheries, Palestine; G. Griffith, (Chemist, Agricultural Department, Uganda), chemist (soils), Agricultural Department, Straits Settlements and Federated Malay States; U. J. Moffat (agricultural officer), senior agricultural officer, Northern Rhodesia; T. G. Strangeways (superintendent of agriculture, Gold Coast), agricultural officer, Northern Rhodesia; C. B. Bisset (field geologist), senior geologist, Uganda; A. E. P. Kershaw (senior inspector of mines), chief inspector of mines, Federated Malay States; E. B. Thomas (inspector of mines, Nigeria), inspector of mines, Federated Malay States; R. H. C. Higgins (veterinary officer), senior veterinary officer, Tanganyika Territory; W. Allan (entomologist), assistant director and entomologist, Agricultural Department, Northern Rhodesia; W. A. Macky (formerly meteorological officer, Malaya), meteorologist, Bermuda.

Announcements

Lord Stamp, chairman of the London Midland and Scottish Railway, and president in 1936 of the British Association, has been appointed adviser on economic co-ordination to a committee of Ministers, under the chairmanship of the Chancellor of the Exchequer, dealing with the co-ordination of departments in relation to economic and financial policy.

Sir Frank Smith, formerly secretary of the Department of Scientific and Industrial Research, has been appointed director, and Mr. R. S. Whipple, chairman of the board of directors of the Cambridge Instrument Company, Ltd., deputy director, of production of scientific instruments, Ministry of Supply.

Sir Joseph Barcroft, Sir Harold B. Hartley and Sir Frank E. Smith have been appointed members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research. The Right Hon. Lord Cadman and Sir James Jeans have retired from the Council on completion of their terms of office.

On account of prevailing war conditions, the Council of the Zoological Society of London has decided for the present to discontinue the fortnightly scientific meetings.

Dr. Joseph Rigney D'Aunoy, dean and professor of pathology, Louisiana State University Medical Centre, New Orleans, has been decorated with the Order of Commendatore of the Crown of Italy in recognition of his achievements in the fields of medical research and education.

On the recent occasion of the celebration of the Mikado's birthday the Empress of Japan gave half a million yen for the foundation of a campaign against tuberculosis.

The following awards of the North-East Coast Institution of Engineers and Shipbuilders have recently been made: Institution Shipbuilding and Engineering Gold Medals to Dr. T. W. F. Brown, of Messrs. R. and W. Hawthorn, Leslie and Co., Ltd., for a paper entitled "Vibration Problems from the Marine Engineering Point of View" (Engineering Medal); Mr. Arnold Emerson, of the William Froude Laboratory, National Physical Laboratory, for a paper entitled "Special Trials of the *Beacon Grange*: the Effect of Steering on Propulsion" (Shipbuilding Medal); M. C. James Memorial Medal to Dr. S. F. Dorey, chief engineer surveyor of Lloyd's Register of Shipping, for a paper entitled, "Strength of Marine Engine Shafting"; R. L. Weighton Memorial Medal to Johan Boele, student at King's College, Newcastle-upon-Tyne; Institution Scholarship for 1939 (value £100) to William Taylor Atkinson, apprentice of Messrs. Richardsons, Westgarth and Co., Ltd., Hartlepool; George Mitchell Harroway Scholarship for 1939 (value £100), to James Dawson, apprentice of Messrs. Smith's Dock Co., Ltd., South Bank on Tees.

Erratum. In Nature, October 7, p. 635, col. 2, second line of legend to the graph, for "1 mol. of $0 \cdot 1$ *M* sugar or ester solution" read "1 ml. of $0 \cdot 1$ *M* sugar or ester solution".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*

Notes on points in some of this week's letters appear on p. 674.

Correspondents are invited to attach similar summaries to their communications.

Evaporation of Built-up Molecular Films

Evaporation of built-up molecular films opens up a promising field of research, and we have applied it successfully in the following cases:

(1) *Determination of condensation coefficients.* The accurately known area[1], and state of molecular orientation[2] of the surface are of great advantage, whilst the evaporation may be readily followed by watching the change in colour. So far we have carried out determinations with films of stearic and arachidic acids deposited on stainless steel slides in the usual manner from a trough adjusted to *p*H 3 by means of acetic acid (no metallic ions present). The films are submitted to high vacuum in a glass tube 'oven' maintained at the required temperature, closed at one end and terminating at the other in an orifice opening into a space immediately connected to the pump, and with a surface cooled by solid carbon dioxide about 5 mm. distant from the orifice. Two films composed of the same number of layers, with areas S_1 and S_2, are evaporated together in ovens with *different* orifice areas A_1 and A_2 respectively. The times t_1 and t_2 required for the complete evaporation of the two films are observed.

Let ν be number of molecules evaporating from a slide per cm.² per sec. into high vacuum ('ideal evaporation'); N be number of molecules per cm.² forming a complete monolayer; $\mu = \frac{N_0}{\sqrt{2\pi MRT}}$ where N_0 is Avogadro's Number, M is the molecular weight and R and T have their usual meanings; α is the condensation coefficient, that is, the fraction of the molecules impinging on the film from the vapour phase which condense; n_1 and n_2 are the number of layers disappearing per sec.; and p_1 and p_2 are the vapour pressures of fatty acid in the ovens.

Now the first film evaporates at a rate $S_1\nu$ but receives molecules by condensation at a rate $S_1\alpha\mu p_1$, so that the net rate of evaporation is $S_1(\nu - \alpha\mu p_1)$ molecules per sec. This rate is also measured by the reduction in the thickness of the film, and is $S_1 n_1 N$ molecules per sec. When a steady state is reached, the number of molecules evaporating per sec. from the film is equal to the number escaping through the orifice in the same time, that is, $\mu A_1 p_1$. Thus

$$S_1(\nu - \alpha\mu p_1) = S_1 n_1 N = \mu A_1 p_1;$$

and similarly

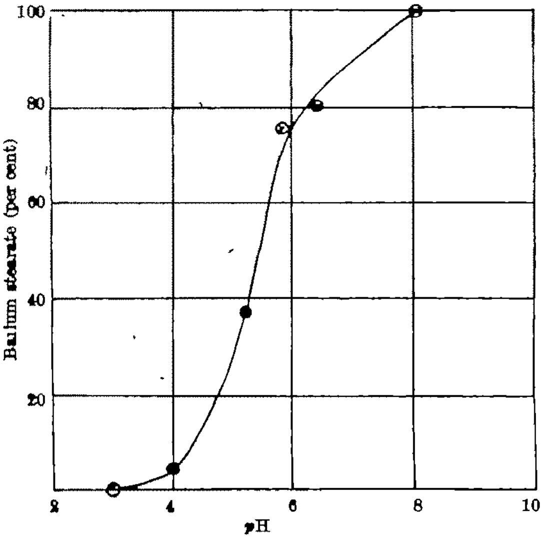
$$S_2(\nu - \alpha\mu p_2) = S_2 n_2 N = \mu A_2 p_2.$$

$$\text{Hence}\quad \alpha = \frac{n_1 - n_2}{S_2 n_2/A_2 - S_1 n_1/A_1};$$

$$= \frac{1/t_1 - 1/t_2}{S_2/A_2 t_2 - S_1/A_1 t_1}.$$

Thus α can be obtained without a determination of the saturated vapour pressure—an advantage since this is of the order of 10^{-5} mm.

Preliminary results show that the values of α for stearic and arachidic acids are both equal to 0·01 ± 0·004. This figure is small, but not improbably so. Alty and Mackay[3,4] obtained 0·17 for camphor and 0·036 for water. Moreover, the most significant factor in producing low α-values is probably the steric or orientation effect (Volmer[5]), and this is certainly of particular importance in the case of fatty acids, consisting as they do of a polar head which must fit into a predetermined place in the lattice, and a very long chain.



It is hoped to extend these measurements to other fatty acids and also to other suitable volatile substances. It should then be possible to throw further light on the correlation between α-values and molecular structure, already tentatively discussed by some authors (Alty[6], Volmer[5]).

(2) *Determination of the free acid content of built-up soap films.* The mixed film is subjected to high vacuum in the oven described above, when the free acid vaporizes and the neutral soap remains. The colour of the film changes owing to the fall in refractive index, and from the values of the initial and final apparent thicknesses, measured by comparison with a standard-step-gauge, the proportions of neutral soap and free fatty acid in the original film can be calculated. Results for barium stearate deposited on stainless steel slides from troughs containing 2×10^{-4} *M* sodium bicarbonate, 6×10^{-5} *M* barium chloride, and adjusted to the required *p*H by the addition of ammonium hydroxide or acetic acid, are given in the accompanying graph. Our values differ somewhat from those obtained by Langmuir and Schaefer[7] for the composition of barium soap films on the *trough* surface—that is, before deposition—

being in fact closer to their values for calcium soaps. The difference may be due to the adsorption of Na+ ions; this was suggested by Langmuir and Schaefer to account for the difference between their own values for barium and calcium respectively. Measurements are in progress for 'soaps' composed of various other metallic and higher fatty acid ions.

Built-up films of volatile substances should also prove useful in molecular ray technique: the rate of effusion can be observed directly by matching the change in colour of the film within the transparent oven as already described.

Large Anisotropy of the Electrical Conductivity of Graphite

Graphite is a hexagonal crystal with a perfect basal cleavage. The carbon atoms in it are arranged in layers parallel to the basal plane, the atoms in each layer forming a regular hexagonal net-work[1]. The distance between adjacent layers is 3·4 A., which is much larger than the distance between adjacent atoms in the same layer, namely, 1·42 A. The crystal exhibits some remarkable magnetic properties. Whereas its susceptibility along directions in the basal plane is about $-0·5 \times 10^{-6}$ per gm., which is nearly that of diamond, the susceptibility along the normal to the plane is more than forty times greater, being equal to -22×10^{-6} per gm. at room temperature[2]. The abnormal diamagnetism along the latter direction shows a striking temperature dependence[2], and is structure-sensitive[3].

Associated with the abnormal diamagnetism along the normal to the basal plane, we should naturally expect a much larger electrical conductivity in the basal plane than along the normal to the plane. On examining the available literature, we find that conductivity measurements on single crystals of graphite have been made along directions in the basal plane only[4]. We have therefore made measurements both along these directions and along the normal to the basal plane, using some well-developed single crystals from Ceylon. We find that the conductivity in the basal plane is at least *ten thousand* times larger than that along the normal to the plane. Whereas the specific resistance in the basal plane is of the order of 10^{-4} ohm-cm., the specific resistance along the normal to the plane is 2–3 ohm-cm.

Life-time of the Mesotron

In a recent note[1], Prof. P. M. S. Blackett seeks to link quantitatively the observed life-time of the mesotron to other constants of Nature. I should like to propose what seems to me a simple and direct deduction of this quantity by relating it to the theory of the nature of the mesotron which I recently advanced[2].

This theory suggests that a heavy electron may be thought of as a quasi-stable state of an ordinary electron moving at a speed such as to enable it to fulfil a simple resonance condition with an atomic nucleus near which it chances to pass. Thus the 'birth' of a mesotron is connected with the approach of a moving electron to within a distance a of a nucleus, where $a \approx e^2/m_0c^2$ represents the range of nuclear forces.

It is natural to assume that, in addition, the annihilation of such a particle may be conditioned by close approach to a nucleus. The mean free path of a very fast electron moving among the nuclei of gas atoms is given by an expression of the form

$$l = \frac{1}{\pi n a^2}, \qquad (1)$$

where n is the number of atoms per unit volume and a has the value given above. Then the life-time of a mesotron moving with essentially the velocity of light will be

$$\tau_0 = \frac{l}{c} = \frac{m_0^2 c^3}{\pi n e^4}. \qquad (2)$$

Substitution of numerical values, using for n the number of atoms per unit volume in air, leads to $\tau_0 = 2·48 \times 10^{-6}$ sec., in remarkable agreement with the experimental value of about $2·5 \times 10^{-6}$ sec.

Speculations as to the fate of the excess energy (mass) of the mesotron upon its annihilation must be reserved until more extensive experimental information is available.

Dipole Moment and Alkyl Chain Length

Baker and Groves[1] have recently determined accurate values for the dipole moments of toluene, ethyl benzene, isopropyl benzene, and tertiary butyl benzene, by the gas temperature method.

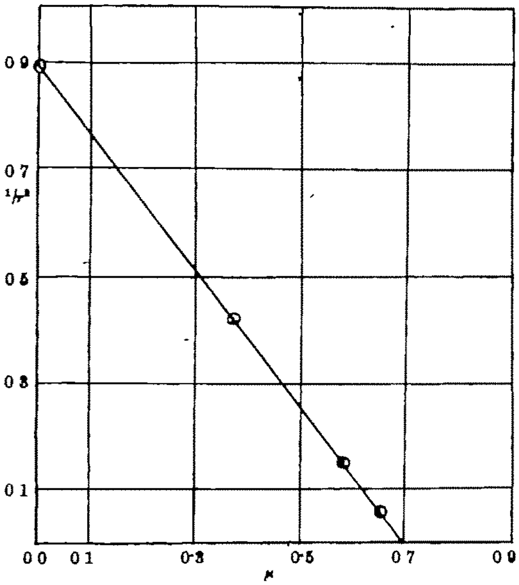
Baker has also pointed out[2] that the observed sequence of dipole moments is represented by a graph of exponential form (μ being plotted as ordinates against arbitrary equal abscissa increments).

Werner[3] has expressed the moments of a homologous series $C_nH_{2n+1}CN$ by means of an exponential series, but no relation exists between dipole moment and side-chain length as a homologous aromatic series is ascended. It is now found that if μ is plotted against $1/r^2$, where r is the distance between the carbon of the ring and the terminal carbon atom (H in the case of benzene) for C_6H_6, $C_6H_5CH_3$ and $C_6H_5.C_2H_5$, a straight line results:

	r_r(A.)	$1/r^2$	$\mu(D)$
C_6H_6	1·06	0·890	0·00
$C_6H_5CH_3$	1·54	0·422	0·37
$C_6H_5C_2H_5$	2·53	0·156	0·58
$C_6H_5C_3H_7$	3·95	0·064	0·65

Limiting value, $\mu = 0·69\ D$.

Extrapolation of this line (see diagram) predicts a limiting value for the dipole moments of the series of 0·69, in good agreement with 0·70 *D* found by Baker and Groves (*loc. cit.*) for tertiary butyl benzene. Assuming also that μ for *n*-propyl benzene is reasonably the same as that found for iso-propyl benzene,



and calculating the root mean square value for r using Eyring's formula[4], $\overline{r^2} = c_1^2 \{n + 2(n-1)\cos\theta + 2(n-2)\cos^2\theta \ldots\ldots + 2\cos^{n-1}\theta\}$, where c_1 is the distance between consecutive carbon atoms and $\theta = 71°$, the figure shows that conformity to the relation results.

Removal of Fluorine from Potable Waters

FLUORINE as the etiological factor in the production of a destructive hypoplasia of human dentition, known as mottled enamel, was established beyond doubt by Smith *et al.* This resulted in a universal recognition of fluorine toxicosis as a public health problem. Numerous methods whereby the soluble fluorine fraction of natural waters can be reduced to a safe level are encountered in the literature. The majority of these methods, however, are costly and impracticable. Several workers reported the value of tri-calcium phosphate as a defluorinizing agent. The solute fluorides are either absorbed or thrown out of solution as the fluoapatite. However, the use of various types of tricalcium phosphate in filter beds in conjunction with waters of high salt content results in a rapid impregnation and inactivation of the active principle. The result is that a continual check on the fluorine content of the effluent water is imperative.

I have observed that in the determination of the titratable acidity of aqueous solutions of superphosphate, the soluble fluorine fraction suffers a reduction. MacIntire and Hammond stressed the possibility of exploiting commercial superphosphates as a source of calcium phosphate to effect the removal of fluorides from natural waters. This method will, however, result in a marked increase in the fluorine content of the water before treatment and a very high subsequent sulphate content of the treated water.

It has been shown in this laboratory that there is a marked reduction in the solubility of both the sulphate and fluoride compounds present in superphosphate at very high aqueous concentrations.

By simply introducing a small volume of the highly concentrated solution into a fluoride-contaminated water and precipitating tricalcium phosphate in a flocculent state in the medium by the addition of lime, the resultant treated water will contain a mere fraction of one part per million of fluorine while the sulphate in solution amounts to a trace. In practice this method of removing fluorine is inexpensive and simple, and gives reliable results.

Myosine and Adenosinetriphosphatase

ORDINARY aqueous or potassium chloride extracts of muscle exhibit but a slight capacity to mineralize adenosinetriphosphate. Even this slight liberation of phosphate is mainly due, not to direct hydrolysis of adenosinetriphosphate, but to a process of secondary, indirect mineralization, accompanying the transfer of phosphate from the adenylic system to creatine, the corresponding enzymes (for which the name 'phosphopherases' is suggested) being readily soluble.

In contrast to this lack of adenosinetriphosphatase in the soluble fraction, a high adenosinetriphosphatase activity is associated with the water-insoluble proteins of muscle. This enzymatic activity is easily brought into solution by all the buffer and concentrated salt solutions usually employed for the extraction of myosine. On precipitation of myosine from such extracts, the adenosinetriphosphatase activity is always found in the myosine fraction, whichever mode of precipitation be used: dialysis, dilution, cautious acidification, salting out. On repeated reprecipitations of myosine, the activity per mgm. nitrogen attains a fairly constant level, unless denaturation of myosine takes place. Under the conditions of our experiments (optimal conditions have not been determined) the activity of myosine preparations ranged in different experiments from 350 to 600 microgram phosphorus liberated per mgm. nitrogen in 5 min. at 37°. Expressed as

$$Q_P \left(= \frac{\mu\text{gm. P}/31 \times 22{\cdot}4}{\text{mgm. N} \times 6{\cdot}25 \times \text{hour}} \right),$$

this gives values of 500–850.
